AURORAL STUDIES WITH TWIN ROCKETS

Ion exchangers from Pharmacia Fine Chemicals

The better choice because ion exchangers from Pharmacia Fine Chemicals have excellent capacities, do not have to be decanted, and require the minimum of preparation.

Better results because ion exchangers from Pharmacia Fine Chemicals are bead formed, making them easy to pack and quick to run. Separations can be repeated many times in the same column.

Better information can be found in the NEW handbook "Ion exchange principles and methods" and the Literature Reference Lists, available free on request from Pharmacia Fine Chemicals.

Get the consultation free. (and the coffee cup, too)

When you buy monoclonal antibodies for research from New England Nuclear, you can be sure they are made and tested to the standards of quality traditional in our radiochemicals. These hybridoma-produced immunoglobulins show exceptionally high specificity and titer, confirmed by assay, with results and other technical data included in your shipment.

Then there are the intangible benefits, which you can easily make tangible by calling us toll free. Our technical staff will gladly share with you the experience we have gained in building this major new product line, including the application and behavior of monoclonal antibodies under experimental conditions.

First let us have your name, so we can send you current product information and place you on our mail list, which guarantees that you'll be kept apprised of new developments. We intend to make this the finest and widest line of monoclonal antibodies available for research use. Please circle the inquiry number, or write.

And, oh yes, the coffee cup. It's free when you become a customer (and quite appropriate for use during your dialogue with our staff).

Not for use in humans or clinical diagnosis

VOLUME 25

Histochemistry and Cell Biology of Autonomic Neurons, SIF Cells, and Paraneurons

Editors: Olavi Eränkö, Seppo Soinila, and Heikki Päivärinta

SECTION HEADINGS: Phenotypic Plasticity and Development of Sympathetic Cells / Fine Structure of SIF Cells and Modulation of Ganglionic Function / Histochemistry and Experimental Cytology of Adrenal Chromaffin Cells and Glomus Cells / Granular Vesicles and Experimental Cell Biology of Sympathetic Neurons and Paraneurons / Immunohistochemistry of Opioid and Other Peptide Neurons in the Autonomic and Central Nervous Systems / Subject Index.

410 pp., 233 figures, $45.00 (August 1980)
ISBN 0-89004-495-3

VOLUME 24

Long-Term Effects of Neuroleptics

Editors: F. Cattabeni, G. Racagni, P. F. Spano, and E. Costa

This volume examines the molecular mechanisms involved in the therapeutic benefits and untoward side effects of the neuroleptic drugs. Emphasis is on the action of chronic neuroleptics on dopaminergic receptors and on neurotransmitter interaction.

660 pp., $58.00 (1980) ISBN 0-89004-405-8

VOLUME 23

Ergot Compounds and Brain Function—Neuroendocrine and Neuropsychiatric Aspects

Editors: Menek Goldstein, Donald B. Calne, Abraham N. Lieberman, and Michael O. Thorner

This volume describes the pharmacology of ergot compounds. It explores the therapeutic implications of the dopaminergic activity of these compounds in the treatment of parkinsonism, the galactorrhea-amenorrhea syndrome, acromegaly, and several neuropsychiatric disturbances associated with aging. Because of the diversity of the applications of these compounds, this book will be of interest to endocrinologists, neurologists, pharmacologists, and gerontologists.

431 pp., $41.00 (1980) ISBN 0-89004-450-3

VOLUME 22

Neural Peptides and Neuronal Communication

Editors: E. Costa and Marco Trabucchi

This volume reviews recent research on the physiological function of neural peptides. Although emphasis is on the endorphins and enkephalins, chapters also discuss other peptides including substance P, somatostatin, gastrin, bombesin, ACTH, prolactin, corticotrophin and somatotrophin, releasing factors, thyrotrophin, gonadotrophins, growth hormone, β-lypotrophin, α-melanotrophin, and cholecystokinin.

670 pp., $57.00 (1980) ISBN 0-89004-375-2

VOLUME 21

Receptors for Neurotransmitters and Peptide Hormones

Editors: Giancarlo Pepeu, Michael J. Kuhar, and S. J. Enna

This volume discusses the structural and biochemical properties, functions, and ligands of most of the known receptors and identifies their common denominators. Sections include: general and electrophysiological characteristics of receptors; purification and regulation of receptors; monoamine receptors; benzodiazepine and GABA receptors; opioid and neuroendocrine receptors; and receptor alterations in aging and disease.

544 pp., $52.00 (1980) ISBN 0-89004-408-2

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp(a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

A no-compromise solution to scanning electron microscopy

The increasing use of scanning electron microscopy in industrial research and product development calls for higher standards and degrees of quantification and improved operational versatility.

Until now however, positional geometry within the specimen environment, along with the many detectors that have to be placed around the specimen, has required an SEM (scanning electron microscope) detector compromise that often produces poor performance in at least one of the operating modes.

So Philips developed a 'no-compromise' scanning electron microscope – the SEM 505 – in which the revolutionary, fibre-optics based, Multi-Function Detector (MFD) interfaces the *detecting elements* with a photomultiplier/pre-amplifier assembly that can be placed outside of the specimen chamber; thus permitting high flexibility in detector placement. The result? Optimum detection performance in all modes because detection geometry is no longer limited by fixed construction or precise port location.

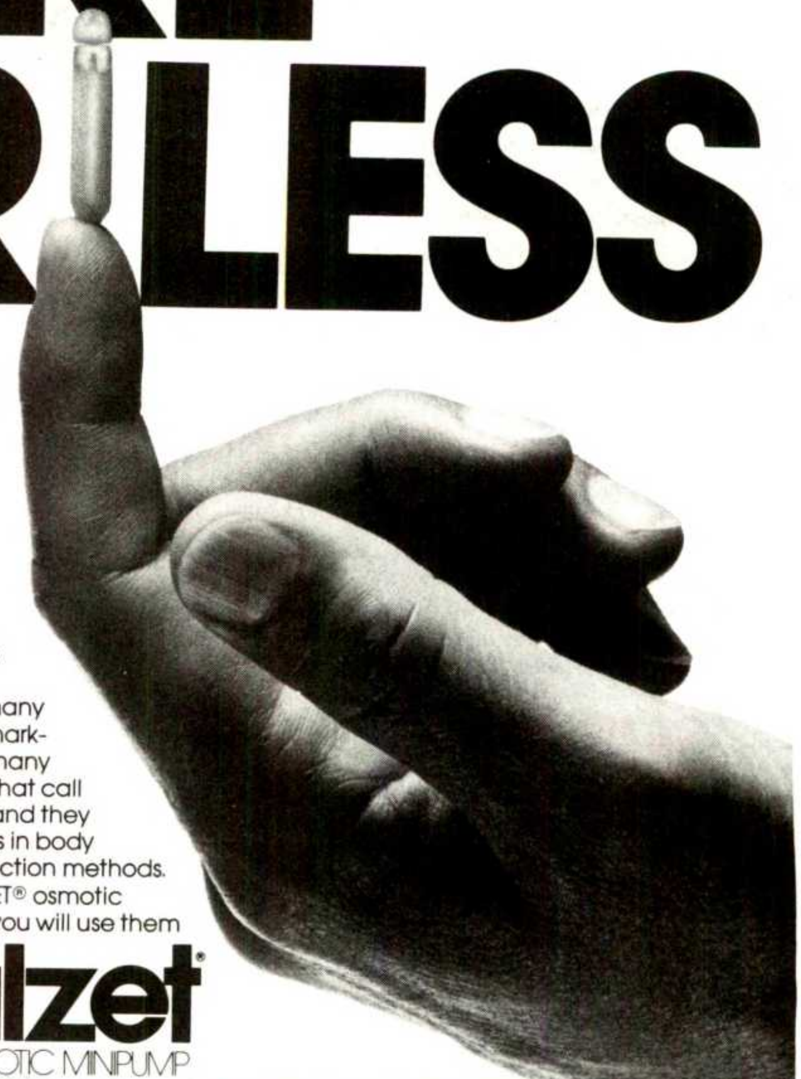
MORE FOR LESS



Alza is pleased to introduce the Model 2002 (.5μ l/hr, 14 days) ALZET® osmotic minipump, the latest edition to the ALZET Model 2000 series. The Model 2002 provides a wider temperature range and solvent compatibility for continuous, stress-free, rate-specified administration of bioactive agents in laboratory animals, or in vitro, than our 1700 series minipumps. And at lower cost.

It costs as little as 47¢ per day (in quantities of 100) to attain the kind of control in plasma or tissue concentrations of bioactive agents that was previously possible only with complex systems of expensive infusion pumps.

There are now over 130 published papers in many areas of bioscience based on the use of these remarkable minipumps. Minipumps have made viable many previously impossible or impractical experiments that call for the continuous presence of bioactive agents, and they avoid the large swings in concentrations of agents in body fluids that accompany ordinary pulse/drench injection methods.

You will want to investigate the use of the ALZET® osmotic minipumps, because they are cost-efficient. And you will use them repeatedly because they contribute to better results. To order minipumps or to receive more information, call our toll-free number: 800/227-9953, or send in the coupon below.

Chromatography monitoring as simple as

A

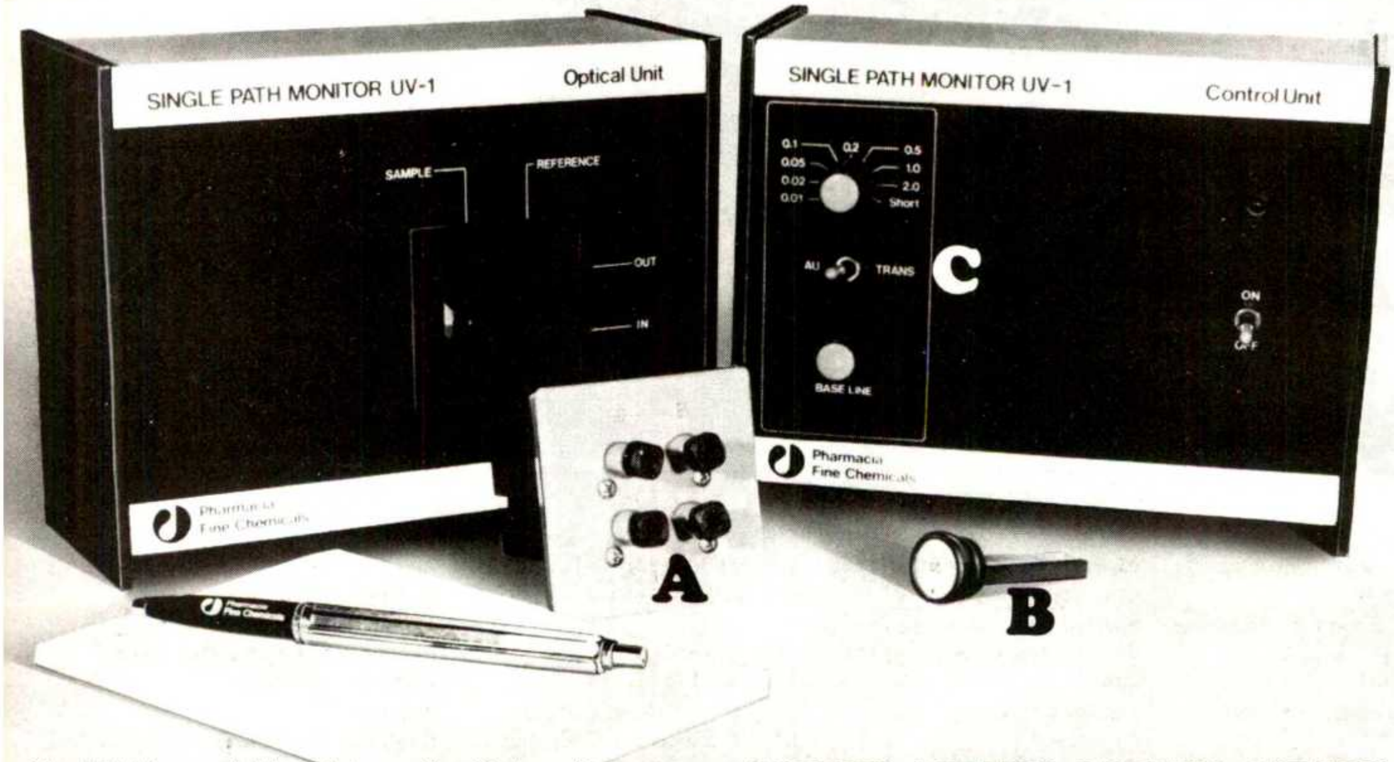
SLIP in a 10 mm or a 3 mm optical path-length cell. These two cells make the UV-1 equally suitable for monitoring in high or low absorbance ranges.

B

SNAP in a 254 nm or a 280 nm filter. The UV-1 provides sensitive and reliable UV monitoring for the detection of proteins, polypeptides and nucleic acids.

C

FLIP a switch for measuring Absorbance or % Transmission. The absorbance setting gives a quantitative linear response at a known sensitivity range and the percent transmission ensures that all peaks remain on scale.



The UV-1 is a reliable, high quality, high performance dual-beam instrument that is ideally suited to your wide range of chromatographic conditions. Ask today for complete specifications on the UV-1 or on the more sophisticated dual sensitivity UV-2 monitor.

NEW! NEW! NEW! NEW!

Now also for monitoring at 214 nm. Available as a complete monitor UV-1/214 or as an optical unit to extend the standard UV-1 to 214 nm.

ORION offers the electrodes, meters, and accessories for every pH measurement you will ever want to make... and more.

ORION offers high-quality glass pH electrodes in nine configurations . . . with many connector types . . . four sizes of virtually unbreakable pH electrodes that never need refilling with KCl . . . eight pH meters from low-cost portable models to microprocessor-based systems . . . filling solutions, buffers, and swing-arm holders.

Beyond the excellent hardware, there is your local ORION distributor. He has the expertise and the desire to help you choose the combination of our pH products that is right for your needs. Contact him, or write for more information.

A Reliable Low-Cost Incubator
Anaerobic or Aerobic Applications
Ideal for Cell Culture

This Modular Incubator Chamber minimises environmental fluctuations (i.e. temperature, gas and humidity) associated with conventional incubators. Once cultures have been sealed inside the chamber, it may be purged with the required gas mixture and placed in a controlled temperature environment. Each chamber is an isolated system, allowing experimental conditions which were previously impractical or too expensive. Chambers and trays are made from rugged, non-toxic, u-v resistant polycarbonate. The trays hold petri-dishes, test tubes, tissue culture flasks, microtitration plates and multidishes. Now available exclusively from Flow Laboratories and their appointed distributors world-wide.

You will have complete control of your collection sequence with the intelligent flexibility of the microprocessor directed Pharmacia fraction collector FRAC-300.

Collect varying fraction sizes in any combination of tubes, scintillation vials and free standing beakers.

FRAC-300 operates in both programmable and conventional modes and can be used in LC or HPLC operations with aqueous solutions or organic solvents.

The FRAC-CC chromatography controller is an accessory to the FRAC-300 which allows you to control valves, peristaltic pumps, and gradient mixers in conjunction with the chromatographic profile to allow automatic sample applications, equilibration of the column, buffer changes, etc.

FRAC-300 and FRAC-CC are integrated components of the total Pharmacia chromatographic system that includes chromatographic columns, a peristaltic pump, UV-monitors, recorders and a wide variety of high performance media for gel filtration, affinity chromatography and ion exchange chromatography.

Make use of this new concept in fraction collection and ask for detailed information today.

LEARNING THROUGH COMPUTERS

D.A. TAWNEY

– an introduction to computer assisted learning in Engineering, Mathematics and the Sciences at tertiary level.

You can teach faster and more thoroughly with the aid of a computer.
This book will tell you how.
Contents: Introduction – CAL in Biology – CAL in Chemistry – CAL in Engineering – CAL in Mathematics – CAL in Physics – CAL in Different Contexts – CAL and Learning Package Design – Computer Aspects – The Cost of CAL – The Evaluation of CAL
This is an essential addition to the standard repertory of teaching methods.
£11.00 0 333 23585 1

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (a) is preferred to e^a if 'a' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

Raven Press *announces a major new journal:*

Journal of Molecular and Applied Genetics

A JOURNAL FOR THE RAPID PUBLICATION OF FULL-LENGTH ARTICLES ON STUDIES UTILIZING MODERN GENETIC TECHNIQUES, ESPECIALLY RECOMBINANT DNA METHODS, TO SOLVE BASIC AND APPLIED PROBLEMS IN GENETICS, BIOCHEMISTRY, MEDICINE, AND AGRICULTURE.

Editor-in-Chief:
Howard M. Goodman, Ph.D.
Howard Hughes Medical Institute Laboratory
Department of Biochemistry and Biophysics
University of California, San Francisco
San Francisco, California 94143 U.S.A.

CALL FOR PAPERS

Manuscripts on the synthesis of biologically and medically relevant proteins, genomic organization, chromosomal gene mapping, gene structure, regulation of gene expression, molecular and biochemical studies on genetic diseases, and plant molecular biology are invited for submission. Consistent with the ideals of the International Editorial Board and of the Editor-in-Chief, only papers of the highest scientific merit and originality will be accepted. Publication will begin early in 1981.

The journal will provide generous space for inclusion of figures, and special efforts will be made to avoid excessive reduction. High quality printing on glossy coated paper will assure faithful reproduction of illustrations. The most modern computer typesetting techniques will facilitate rapid publication. The Publisher will be Raven Press, New York. All manuscripts should be submitted to the Editor-in-Chief as noted above. Instructions to contributors are available from either the Editor-in-Chief or from Raven Press, 1140 Avenue of the Americas, New York, N.Y. 10036, U.S.A.

SUBSCRIPTION ORDER FORM

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

A no-compromise solution to scanning electron microscopy

The increasing use of scanning electron microscopy in industrial research and product development calls for higher standards and degrees of quantification and improved operational versatility.

Until now however, positional geometry within the specimen environment, along with the many detectors that have to be placed around the specimen, has required an SEM (scanning electron microscope) detector compromise that often produces poor performance in at least one of the operating modes.

So Philips developed a 'no-compromise' scanning electron microscope – the SEM 505 – in which a revolutionary, fibre-optics based, Multi-Function Detector (MFD) interfaces the detecting elements with a photomultiplier/pre-amplifier assembly that can be placed outside of the specimen chamber; thus permitting high flexibility in detector placement. The result? Optimum detection performance in all modes because detection geometry is no longer limited by fixed construction or precise port location.

Chromatography monitoring as simple as

A

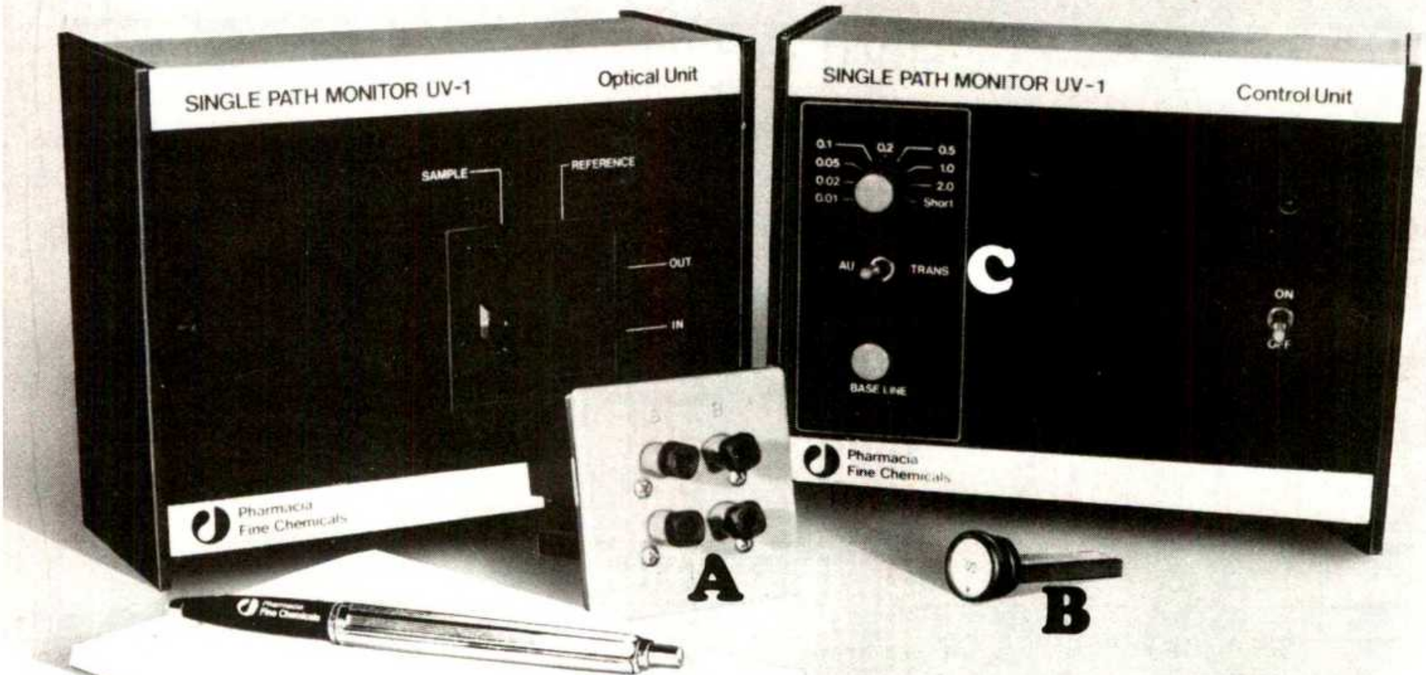
SLIP in a 10 mm or a 3 mm optical path-length cell. These two cells make the UV-1 equally suitable for monitoring in high or low absorbance ranges.

B

SNAP in a 254 nm or a 280 nm filter. The UV-1 provides sensitive and reliable UV monitoring for the detection of proteins, polypeptides and nucleic acids.

C

FLIP a switch for measuring Absorbance or % Transmission. The absorbance setting gives a quantitative linear response at a known sensitivity range and the percent transmission ensures that all peaks remain on scale.



The UV-1 is a reliable, high quality, high performance dual-beam instrument that is ideally suited to your wide range of chromatographic conditions. Ask today for complete specifications on the UV-1 or on the more sophisticated dual sensitivity UV-2 monitor.

NEW! NEW! NEW! NEW!

Now also for monitoring at 214 nm. Available as a complete monitor UV-1/214 or as an optical unit to extend the standard UV-1 to 214 nm.

LINCA SCIENTIFIC INSTRUMENTS

TUBINGLESS CELL HARVESTER - 92.070

A new inexpensive and clog-free device for the rapid harvesting of cells from micro-culture plates.

Pat. Pending.

MULTIPLE MEMBRANE FILTERS - 92.051/052

Instruments for rapid processing of a large number of radioactive samples for collection of filtrates and/or precipitates.

U.S.A. Patent No. 3,888,770.

YEDA PRESS - 92.049/050

Devices for the controlled disruption of biological material under conditions which maintain biological activity. 28 ml. and 250 ml.

U.S.A. Patent No. 3,679,139.

ELECTROPHORESIS INSTRUMENTS AND POWER SUPPLIES

Flat plate and other electrophoresis instruments. Interesting range of stablized power supplies, 0-500 VDC. Also "constant" power supply.

Linca Lamon Instrumentation Co., Ltd.

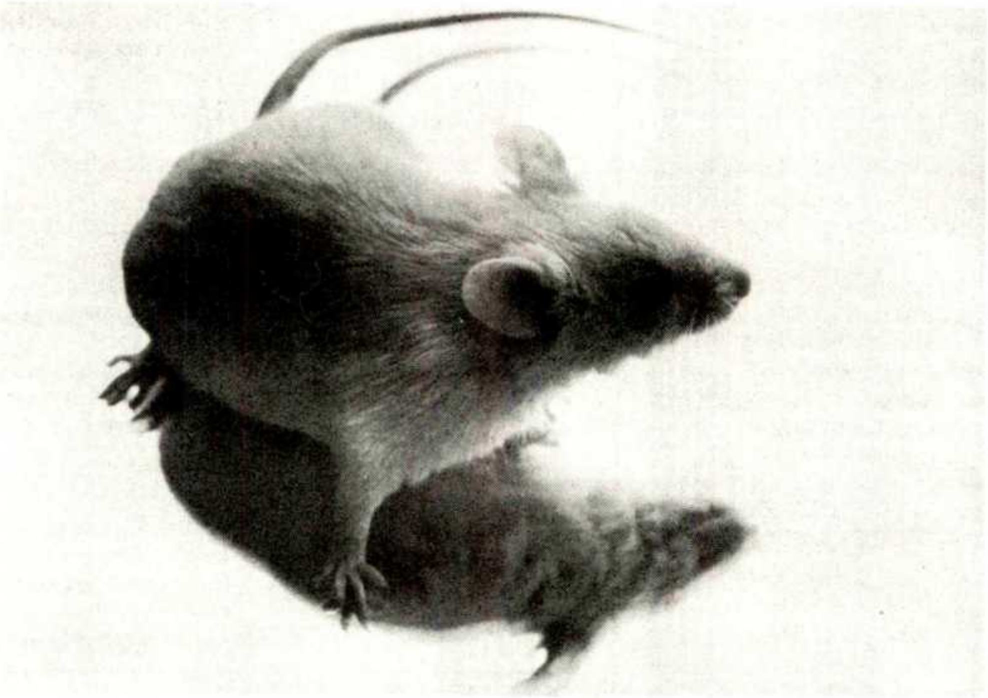
Anti hLH Anti hCG Anti hAFP

MONOCLONAL ANTIBODIES



Medix has developed monoclonal antibodies produced by hybridoma cell lines. Our profound experience in these techniques enables us to produce large amounts of truly monoclonal antibodies always having indentical properties.

AVAILABLE
Anti hLH Anti Human Luteinizing Hormone
Anti hCG Anti Human Chorionic Gonadotropin
Anti hAFP Anti Human Alpha-Fetoprotein
Suitable for immunoassays,
affinity chromatography,
immunohistochemistry etc.

Medix is continuously developing new monoclonal antibodies. We are also ready to discuss preparation of special monoclonal antibodies for customers.

Future for unprofessional societies

One of the curious attributes of the English speaking world is its rich endowment of societies dedicated to advancement of science. The oldest among them have their roots at the end of what the historians call the Age of Improvement, the period spanning the end of the eighteenth century and the beginning of the industrial revolution. People all over the world then imagined prosperity could indeed be wrung from the careful application of technology and that profound social transformation might thus be brought about. The Napoleonic War appeared not to stifle optimists in Britain, while the haunting social dilemmas of the mid-nineteenth century had not been foreseen. What more natural then that people of goodwill should band together in societies for the development of science and technology? The result, still apparent, was the creation of a host of informal scientific societies as different as the Royal Institution (in London) and the American Philosophical Society (in Philadelphia) on the one hand and the British and American Associations for the Advancement of Science on the other. Although, with the passage of time, that part of the original role of these societies concerned with the communication of original science has now been taken over by the professional disciplinary societies that abound, many of them continue and even flourish. Why should this be and what role do they have to play in the decades ahead?

These questions are prompted by the arrival of the season in which the societies for the advancement of science hold their annual conferences. The British Association is meeting this week in the city of Salford (often wrongly called the slummy part of Manchester; the two cities, although contiguous, are constitutionally independent). The American Association will be meeting next January in Toronto, thereby demonstrating that the days have long since gone when members of the British Association would take to ships to hold their annual meetings in distant parts of the British Commonwealth. Instead, the example of the British Association has spawned similar organizations in India, Australasia and South Africa. In the next few months these informal societies will also be holding their annual meetings, somewhat formless gatherings attended by a few thousand people (but the organizers always hope for even more). The perpetuation of these ceremonies, even though they play no significant part in the exchange of information between professional scientists, is a sign that they must serve some purpose. What can that be? How might it be strengthened?

Casual observation, as at Salford this week, suggests several entirely beneficial functions of the unprofessional societies, of which the chief is that they are genuinely unprofessional. They provide the opportunity for people with diverse interests in science to hob-nob with people straight from the laboratory, and thus to learn a little more directly than would otherwise be possible what is happening at at least some parts of what Vannevar Bush called "the endless frontier". To be sure the frontier is covered only patchily at these huge gatherings, which also unhappily provide opportunities for the announcement of "discoveries" that would not filter through the usual refereeing processes by which articles in the scientific journals are judged. On balance, however, the opportunity to learn about science from at least some horses' mouths is much valued by those who attend the meetings and is also a wider public service. Many of the participants are people who teach in schools, or who are similarly isolated from the part of the scientific profession in which they learn their trade; nobody will dispute the importance of any means that helps such people to stay in touch. In recent years, all the unprofessional societies, but the British Association in particular, have also found that young people — students and would-be students — have been the most lively participants at annual meetings. This is yet another sign that the unprofessional societies perform a valuable social function. The suggestion that the annual meetings might also lead to more general enlightenment through the general press is now less true than in the past; most newspapers regard their responsibility with continual seriousness and do not require such meetings to maintain their awareness. Even so, the unprofessional societies obviously render a service both to their members and, in some ill defined way, to the larger public. Why not, in the circumstances, let them get on with what they consider their business in the way they think best?

Unfortunately, that is too much to ask. To the extent that the unprofessional societies ask that public attention should be paid to what they do, public interest in how they set about their work is unavoidable. The case of the British Association is especially difficult, for since the Second World War, the Association has been living from hand to mouth, badly equipped for the job it seeks to do, too dependent on the goodwill and generosity of the cities (and their universities) in which it seeks to hold its annual meetings and on industrial companies and local authorities for the funds to support its regional activities and, most recently, on public funds (administered by the Royal Society) for the cost of running its tiny central office. On the half-a-dozen occasions in the past three decades, on which the cry of threatened bankruptcy has been heard, the Council of the British Association has resolved that radical changes of some kind must be made. And then, perhaps just too soon, funds have appeared from somewhere and have ensured that the changes made are neither radical nor, as it happens, effective. The result is that the British Association stumbles on, from one annual meeting to the next (or, with luck, the next but one) with a part-time Chief Executive Officer and an organization designed to ensure that decisions are made only slowly and half heartedly.

On the face of things, at least, the American Association for the Advancement of Science (AAAS) is in much better shape. Over the years, it has become a successful publisher, first of the distinguished scientific journal *Science* (whose 100th anniversary falls this year) but more recently of the popular journal, *Science 80*. With such a sheet anchor, the AAAS can provide for its own housekeeping and is even strong enough to compete for grants from federal agencies to enquire into matters as different as the renewal of the school science curriculum and the ethical problems (such as they may be) of new techniques in biology and medicine. With this financial symbiosis between its publishing and its public service the AAAS is relatively immune from outside criticism. Yet the organization is not nearly as successful as it might be. Like its British equivalent, the American association is hamstrung by the way in which its organization is built around a notion that there should be different sections of the society for the various disciplines that are from time to time invented. There is, of course, nothing wrong with the concept of disciplines within science but it is especially incongruous that disciplinary interests should be so firmly entrenched in societies claiming that they are essentially interdisciplinary. The fact that the officers of the hosts of sectional committees of the AAAS are elected publically, not nominated by taps on the shoulders from old chums in the British way, does not make the American organization more flexible, but the opposite. The outcome in both cases is that the societies for the advancement of science are usually too slow off the mark in

0028-0836/80/36001-02$01.00

causes that might help to advance science, too inhibited (by their constitution) even from having views on many important matters and yet, paradoxically, whimish — too much inclined to react unpredictably to changing circumstances and changing needs.

This complaint, harsh though it may seem to the devoted people who work hard at making the unprofessional societies function, is, nevertheless, quite fair. For what, in the past few years, have these societies done to help resolve some of the important problems in their declared fields of interest? Issues such as the hazards (if any) of genetic manipulation, public policy on nuclear power and even public policy towards the universities, may have been mentioned at the annual meetings of the British and American societies, but neither organization have used the diversity of its membership hammer out possible solutions. Providing a forum for opposing views on such issues is much easier, but also much less valuable, than attempting to resolve conflicts of opinion in ways that will carry conviction in and outside the scientific profession. Providing opportunities at the annual meetings for well known people to put their well known views on grand subjects such as "Energy", "Population" or "Food" is similarly a largely unproductive enterprise. So how should the unprofessional societies put their houses in order? The most urgent need is that they find a way of tackling problems that at present impede the advancement of science — for one example see below. Organizations that cannot constitutionally have a view on issues such as the organization of research or the safety of nuclear power (and which may not even have studied them) can no longer claim to assist the advancement of science. The unprofessional societies have also been known to make links with their unprofessional constituencies — school teachers, industrial scientists and the like; this, however, is a task that could and should be tackled. (Both the Americans and the British societies will protest that many of their members are teachers, but that is not the same thing.) To accomplish these and other goals will undoubtedly require that the organizations themselves should change, perhaps substantially, but there is no reason to suppose that the change need be so drastic that the valuable aspects of what they do at present would be jeopardized.

Public-key cryptography muddle

The National Science Foundation and the National Security Agency in the United States are making a frightful muddle for themselves by their new policies on academic research in cryptography, made public last week. This is not the first time that there has been trouble between academic cryptographers and the United States Intelligence Agencies. Four years ago there was a minor storm when it turned out that an official of the security agency had written to the (American) Institute of Electrical and Electronic Engineers suggesting that articles on the design of new codes should not be published in the interests of security. Eventually, the row died down only when the official concerned was said to have written in a personal capacity. The latest development is more serious. The National Science Foundation and the National Security Agency have apparently reached an understanding on the processing of future research grant applications in cryptography. The National Security Agency will, it seems, now see all applications in the field that may be sent to the National Science Foundation and will, if it thinks fit, back good projects with its own funds. One consequence may be that more funds are available for research cryptography, which might lift the spirits of the academics in this field. Another is that the National Security Agency may attach to research grants the condition that the results should not be published without prior agreement from the intelligence people, a prospect that will dismay academics.

Is all this, then, a sinister plot to muzzle scientific research in the absence of legal instruments or 'classified' data as in the years immediately after the war? This is one reading of the new arrangement. Whatever the objectives of the National Security Agency the most likely consequence of the Washington agreement will be to make a monkey of the two partners, the National Science Foundation and the National Security Agency. The pace of academic research in this novel field is unlikely to be impeded. Publication, it is hoped, will continue without hindrance. And nobody's national security will be endangered.

What offends the intelligence people is the whole concept of public-key cryptography. They earnestly wish that it had never been invented. The notion is simply that of an unsymmetrical coding system, one in which it is not possible to infer the key for decoding a message in cypher from a knowledge of the rule by which coded messages are themselves produced from ordinary text. Consequently, with these novel codes, instructions for turning messages into codes could be published in the newspapers and it would, nevertheless, be impossible for somebody intercepting a coded message to decipher its meaning. For most people, the difficulty is that of understanding how there can be codes whose writing and reading keys cannot instantly be inferred one from the other. The demonstration theorem required to dispell this scepticism has now been amply proved, most conspicuously by Professor L. J. Adelman of the Massachusetts Institute of Technology. The feasibility of the new coding system depends on the power of their computers now in service, which can use exceedingly complicated rules to turn ordinary text into coded messages. The basis of public-key cryptography is that the unpublished reading key cannot be inferred from the publishable writing key except with such a gigantic commitment of computer power that nobody in his senses would attempt the job.

Plainly, the National Security Agency is unconvinced. How can it be, these men in dark glasses whisper to each other, that a person can write in a code but be unable to decipher his own coded message? Somebody, they suspect, is pulling their legs. And they also appear to have forgotten that unsymmetrical coding systems, like those now being developed, are precisely the instruments needed to make commercial as well as military computer systems private and immune to espionage. Hitherto, there has been no means by which, for example, banks using public telex systems to transmit confidential information can have done so except by the old-fashioned methods of classical cryptography in which the intended recipient of a message is first provided with a secret code book. With the new codes, in principle at least, the writing key can be made freely available and the recipient of coded messages, the only one with access to the reading key, will be the only one able to decipher. The same techniques can and no doubt will be used to safeguard the privacy of personal data stored in central computing systems. The commercial importance of developments such as these is so self evident and so great that now that the potential value of public-key cryptography is appreciated, nothing will prevent the commercial computer companies from working hard towards the development of practical systems. Even if funds for research are not forthcoming from the National Science Foundation, there will no doubt be eager sponsors for academic research in the field of cryptography among the potential commercial users. For many academics however, the commercial sponsorship of research may be as irksome as the possibility that publication could be restricted — as the National Security Agency may choose to do. In practice, however, the sums of money needed in these fields are not large. The importance of free publication is self evident; quite apart from the intrinsic value of the new coded system, this is also a time when interest in the new field of cryptography needs to be stimulated. Is this not eminently a field in which private foundations should step in?

Carter pledges support for research

Washington

Reversing its policies of only a few months ago, the Carter administration has pledged that, if the President is re-elected in November, it will provide sufficient extra funds for basic research to guarantee a real growth of three per cent in both 1981 and 1982.

This would be achieved by requesting from Congress an additional $600 million over the budget request already submitted for the fiscal year 1981 and which it had previously been proposed to request for 1982. The net result, according to Dr Frank Press, director of the Office of Science and Technology Policy (OSTP), will be to generate a real growth in basic research of about 11 per cent between 1978 and 1982.

The proposal to increase support for scientific research came as part of a general package of measures proposed by President Carter last Thursday, designed to revitalize the US economy through stimulating private and public investment.

Eschewing the major cuts in private taxation that have already been proposed by Republican presidential candidate Ronald Reagan, President Carter is proposing a more specifically geared programme that would reduce the tax burden on certain parts of industry and provide selective support for others.

In a speech outlining his general proposals, President Carter said that it was important to promote technological advance through support for research since it provided a large proportion of productivity growth and also "can create literally millions of jobs in the years ahead."

According to Dr Press, the precise distribution of the extra funds — about $225 million of which are expected to go for the extra support of basic research in the fiscal year 1981, which begins in October — will be discussed with leaders of the university and business research communities.

However the initiatives will include:

- Increased support for areas of "targeted" basic research with broad potential applications. Examples provided by Dr Press included the contributions of genetic research to agriculture, and the basic research necessary to support the next generation of microcomputers.
- Increased support for university-based and other "generic technology centres", proposed in last year's domestic policy review of industrial innovation, and already under active consideration in Congress.
- Greater collaboration between government and industry in promoting the long-term growth of particular industries. The model of the Co-operative Automotive Research Project, looking at basic problems in long-term automobile engineering, may be applied to other areas. Possible similar projects under consideration include cooperation with the steel industry on developing new techniques for producing highly specialized forms of steel, and with the mineral extraction industry.
- An additional $50 million will be provided to upgrade research and teaching equipment in universities. A recent report produced by the American Association of Universities showed that in the university sector, the average age of equipment was about twice that in the industrial sector. The new money, some of which was proposed in the President's original January request as part of the National Science Foundation budget but cut out in the March review, will support what Dr Press calls a "long overdue" renovation of research facilities.

Research and development investment in the private sector will also benefit from the new tax incentives which President Carter said that he proposes to introduce next year. In particular, this speeds up and simplifies the depreciation allowance on investment for research and development equipment, part of a general effort to persuade industry to invest more of what it earns in new technology.

"We are really trying to do two things

Congress falls in line on 1981 funds

Washington

With an election coming up, and few pretending that a balanced budget remains either a feasible or a desirable goal, Congress has taken several actions in the past few weeks indicating a general acceptance of the strategy of the Carter administration in support of research.

Indeed in many cases congressional actions on the research budgets of federal agencies have restored funding to the level of the original budget request put forward by President Carter in January, before being cut back in the budget review in March. Recent actions include:

Physics: Following an unsuccessful attempt by the House of Representatives appropriations committee to cut out any increase in support of basic energy sciences in the Department of Energy — which includes high energy and nuclear physics — the equivalent Senate subcommittee has proposed various increases.

In high energy physics, for example, where the administration had requested in March a total of $354 million for operating, equipment and construction costs, the House committee had recommended cutting this to $327 million. The full House, however, subsequently amended this to $343 million; and the Senate subcommittee last week agreed to propose $359 million, the original request in January.

A similar pattern of changes is seen for nuclear physics, where the administration had requested $111 million, the House agreed to $106 million, and the Senate subcommittee is proposing $113 million.

Physicists are optimistic that the Senate's actions will avoid extra delays in the construction of Fermilab's energy-doubler, and any severe cut in operating expenditure next year, both of which had been widely feared. "No one thought we could come close to these figures," said one university lobbyist last week.

Biomedical research: Although its largesse has not been as great as in previous years, the House of Representatives voted last week to raise the administration's proposed 1.7 per cent increase for basic research in the National Institutes of Health to 5.5 per cent, reaching a total of $3,616 million.

The House accepted the administration's argument that a central feature of NIH support should be maintaining the level of competitive research grants at about 5,000 awards a year. However it disagreed that training grants should be cut back in favour of research support, and much of the money added to the NIH budget will go towards postgraduate support.

National Science Foundation: The House voted last month to provide the NSF with the full $1,074 million that had been requested by the administration, although subsequently agreeing to a 2 per cent cut across the board for all the agencies listed in the composite appropriations bill which includes the NSF.

The Senate appropriations subcommittee has also accepted the administration's request recommending a budget of $1,079 million. In addition to shuffling $5 million from basic research to science education (for which the House has allocated an extra $10 million), the Senate subcommittee is proposing to add an extra $5 million to cover the increased fuel cost being experienced by the NSF's Antarctic research programme.

Department of Defense: So far, the House of Representatives has accepted most of the 20 per cent increase in defence support for basic research requested by the administration. However the equivalent Senate committee is still to act; and there are rumours that cuts of the order of $30 to $50 million — which would reduce the growth rate to the expected rate of inflation — are being considered. **David Dickson**

0028-0836/80/360003-02$01.00

with this extra money," said one OSTP official. "Firstly to help underpin the general research base of the private sector. And secondly to support research, orientated towards the products and processes that are likely to be in place in the next few years."

According to Dr Press, the commitment to additional funds will "restore and go beyond the cutbacks proposed last March, which appeared to wipe out any hope of a real growth in support for basic research in the immediate future".

So far the scientific community has given the announcement a cautious welcome, but is waiting until more specific details are announced in the President's budget request next January — if he is re-elected — before passing judgement.

Although the total amount of funds may be small in comparison with the total US research and development effort, their effectiveness will depend on the way they are packaged. According to Dr Jack Crowely of the Association of American Universities "if they are willing to make some difficult decisions and focus funds in high priority areas, then they could achieve quite a bit."

Little direct reference has been made to research funding in the platform statements of the two main political parties. However the Republican statement does refer to the need to increase support for research and development as part of a general effort to increase US military strength.

NIH funding

Congress control

Washington

Despite intense opposition from the biomedical research community, the House of Representatives last week passed a bill which would, for the first time, give it direct responsibility for the budgets and research programmes of nine out of the eleven National Institutes of Health.

At present only two of the institutes — the National Cancer Institute and the National Heart, Lung and Blood Institute — are covered by specific authorizing legislation. The others fall within the broad responsibilities of the Department of Health and Human Resources.

The new bill sets generous budget ceilings for the various institutes, each of which would have its budget authorized by Congress every three years. Overall, the bill recommends a 27 per cent increase in the NIH budget in 1981 to a total of $4,076 million, almost twice the budget increase proposed in the appropriations bill which was also passed last week (see page 3).

However, the implications of the legislation are that Congress will be in a position to exert more direct control over the research programmes of the nine institutes which currently are not controlled by separate legislation. And it is this which has given rise to strong opposition from universities, medical schools and professional associations.

Writing in the *Washington Post* on 25 August, for example, two days before the vote took place on the bill, the past four directors of NIH stated "We are convinced that a long-term federal commitment to research is far and away best served by permanent authority of the type contained in . . . the Public Health Service Act."

The bill has been opposed by the American Association of Medical Colleges, the Association of Professors of Medicine, and the Joint Health Committee of the Association of American Universities. It has also been the source of fierce controversy within the administration. Initially it was opposed by Health Secretary Mrs Pat Harris, who argued that existing legislation was adequate to ensure a high standard of medically important research. Subsequently, however, after various modifications to the bill, the administration agreed to support the new legislation.

NIH administrators, who had previously been among those in opposition, were instructed to hold to the party line (*Nature*, 22 May 1980). And when the bill was introduced last week by Representative Henry Waxman, chairman of the health and environment subcommittee of the House Interstate and Foreign Commerce Committee, he said that both Dr Donald Fredrickson, director of NIH, and Dr Julius Richmond, the Surgeon General, had written giving their support.

Scientists fear that, by giving Congress access to detailed decisions on research priorities, the process could become over-politicized, encouraging short-sighted mandates to explore applied uses of research at the expense of basic research. However, during last week's debate on the bill, a number of congressmen spoke of the need to be in close contact with NIH, programmes.

Despite an intense lobbying campaign by university and medical school scientists, the proposed legislation was passed in the House by 292 votes to 48. It must now be reconciled with a counterpart bill which has been approved by the Senate, promoted by Senator Edward Kennedy.

This does not create authorizing legislation for all NIH institutes, but mandates the creation of a Presidential Commission on Biomedical Research with broad responsibilities to oversee medical research priorities.

David Dickson

Soviet academics

Wasted talent

Soviet planning is still not making sufficient use of the academic potential of the country, according to V. Kirillov-Ugryumov, Chairman of the Higher Attestation Commission (*Vysshaya Atestatsionnaya Komissiya*-VAK) of the Council of Ministers of the USSR. In a *Pravda* article reviewing the work of VAK over the last five years, he pointed out shortcomings not only in VAK's work of awarding higher degrees, but also in the use made of the content of theses. The annual surveys, provided by VAK, of the content of theses and research projects, are not being utilized by the ministries and planning bodies concerned, and the recommendations made to the State Publishing Commission concerning the publication of the most interesting and significant theses are not being implemented. All this, he says, hinders the implementation of research results in the economy. The problem, moreover, is a particularly pressing one now that the country is on the threshold of the Twenty-Sixth Party Congress which will approve the directives for the next five-year plan.

Not, however, that VAK itself escapes without criticism. Six years ago the Central Committee of the Communist Party of the Soviet Union (CPSU) and the Council of Ministers of the USSR approved a resolution which overhauled the whole system of awarding higher degrees, in particular setting up a network of expert councils to assess theses submitted to them. Not all these councils, said Kirillov-Ugryumov, are functioning properly. In 1979 the presidium of VAK had to return no less than 256 works to the relevant councils since the reports on them were "insufficiently clear or well-grounded". Occasionally "ill-will" is creeping into the work of the councils, interfering with objective scientific assessment, and creating a situation resembling a court of law. Kirillov-Ugryumov goes on to decry "subjectivism and red-tape at any stage of the attestation process".

Nowhere in his article does Kirillov-Ugryumov mention a clause in the 1976 Resolution which many Soviet academics found disturbing — the stipulation that the postulants must satisfy VAK not only with the worth of their theses but also with their political record. Indeed, his criticism that certain expert councils have been letting "weak theses" through, and that steps must be taken to remedy this may well be a veiled criticism of councils which look over-leniently on the mediocre efforts of the scions of high party officials. However, a *samizdat* essay by Grigori Freiman recently republished in the West, *"It seems I am a Jew"* contains what is claimed to be a stenographic transcript of an "expert council" meeting, in which remarkable feats of dialectic are produced to find some reason, other than the postulant's Jewishness, to reject a thesis which all participants know in advance cannot be accepted. If Freiman is to be believed — and at the time of writing he was a Professor of the Kalinin State University, and a member of the CPSU — the political clause is apparently being applied under some other guise.

European coal industry

Conversion plans

Plans for commercial coal gasification plants in West Germany will be complete by December, and liquefaction plants by next autumn, the Federal Ministry for Science and Technology has announced. But because German coal is very deep and very expensive, the intention is more to take a lead in the world market for such technology, than to make much use of it in Germany. So, although the construction of 14 coal refining pilot plants costing £3 billion is under study, Research Minister Volker Hauff said last week that oil and gas derived from coal would supply only 3 per cent of Germany's oil and gas needs in 1990.

Germany was forced to develop gasification and liquefaction techniques during the Second World War to provide the country with fuel, and although the technology then became uneconomic compared with cheap Middle East oil, the industry survived through massive exports to South Africa. After a lull in the sixties, German efforts were revived by the oil price rise of 1973. The United States have since spent more on developing new approaches and principles, but Germany appears to be taking a lead with real plant. German spending on research and development of new coal technologies (including remote extraction) is high, taking the lion's share of the non-nuclear energy research programme, which in turn costs some £230 million a year including industrial participation.

In the United Kingdom, investment is nowhere near so great. British Gas has just placed the contract for one pilot gasifier, using a mix of technologies and capable of converting coal dust and lump coal, at a cost of around £14 million; but this can be set against British Gas profits of some £426 million last year alone on retailing North Sea gas. The National Coal Board (NCB) has less to spend, but has recently recommended the construction of two pilot 1 tonne per hour liquefaction plants, one using the liquid solvent extraction process and the other "super-critical gas extraction"; the cost would be £50 million shared between the NCB, British Petroleum, and the Department of Energy.

However, according to an NCB scientist, the British technology is unique in aiming to produce nearly 100% conversion of the coal into high quality transport fuels, plus some liquid petroleum gas and synthetic natural gas. The technology could provide enough impetus to resist penetration of the British market by German or US technology, and might even provide export potential. The world market in sophisticated coal technologies is expected to reach billions of pounds a year in the 1990s, when oil prices rise to a level which would make coal competitive.

Robert Walgate

Hunter turned hunted

According to the Royal Society for the Protection of Birds at least 17 young peregrine falcons were stolen from UK nests this year. With peregrines selling to falconers at up to £1,500 each, nest robbery threatens to reverse the trend towards restoration of the UK breeding population which was severely affected by organochlorine pesticides twenty years ago. Present legislation prohibits the taking but not the keeping of wild birds. But the UK government has just announced plans to legislate against keeping also; it would require all birds of prey in legal captivity to be registered and ringed.

Third World energy

World Bank aid

Washington

Substantial new funds for energy research in developing countries could be one outcome of the proposals announced by the World Bank in Washington last week to help these countries meet their rapidly escalating fuel bills.

The main focus of the Bank's proposals would be the setting up of a new capital investment fund, which would raise money from private banks and lend it to Third World countries for energy projects ranging from nuclear power stations to conservation programmes.

At the same time, however, ideas for sponsoring relevant lines of research are being discussed. One possibility is that an independent fund or institute for research in renewable energy technologies could be established, perhaps taking a cue from the international group of agricultural research centres whose support the Bank currently coordinates.

In addition to the practical problems caused by energy shortages, World Bank officials have been worried that rising energy costs have made it increasingly difficult for many developing countries to pay off their international debts.

In Brazil, for example, the cost of imported petroleum rose from 12 per cent of export earnings in 1973 to 50 per cent last year; in India the increase was from 22 to 60 per cent over the same period.

The result, according to the *World Development Report, 1980* published by the Bank two weeks ago, is that major oil-producing countries will run current account surpluses of about $110 billion in 1980, while the oil-importing, developing countries will have a combined deficit of more than $60 billion. Efforts have been under way for some time to recycle the surpluses to ease the burden on developing countries. The political importance of this was agreed at the economic summit of western leaders in Venice in June.

The World Bank has been watching the situation closely since 1977 and has started making loans for energy projects. This year, following particularly steep price rises, the Bank's president Mr Robert MacNamara asked his staff for a special report on what additional steps might be taken. This report, including sections on conservation and renewable energy sources, was recently made public.

Its main proposal is that the Bank should set up a special affiliate to raise sufficient money on the private capital market to almost double the $13 billion in loans which the Bank itself intends to make over the next five years on energy projects. This should be sufficient to seed an additional $75 billion in bilateral loans, and concessional terms might be arranged for the poorer countries.

The Bank says that many of the projects it already finances show a high return on investment, sometimes up to 30 or 50 per cent. But in many countries difficulty in raising capital has resulted in only superficial efforts to seek oil, and therefore "not enough research and money have been put into the effort to establish whether there are smaller deposits that could make important contributions to their own energy supplies".

Reversing its earlier opinon, the Bank says that it now agrees that conservation programmes offer a substantial potential for cutting back energy needs.

The proposals will be discussed when the World Bank and the International Monetary Fund meet in Washington later this month. However, it is generally believed that Mr MacNamara already has informal commitments that at least part of the money can be raised.

The precise nature of the fund, however, is still open, and so too are details of the way in which money might be used to finance research — although according to World Bank officials one of the biggest needs is the collection and evaluation of performance data about new energy

0028-0836/80/360005-02$01.00

technologies that have already been developed.

The World Bank's report refers to the need to strengthen the national energy research programmes of developing countries, in particular their capacity to adapt developments made elsewhere. And it also says that attention should be given "to the possibility of organizing international programmes on specific renewable energy technologies".

David Dickson

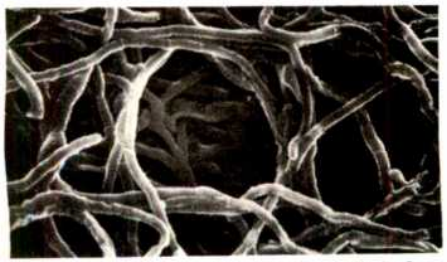
Meat substitutes

Fungal food

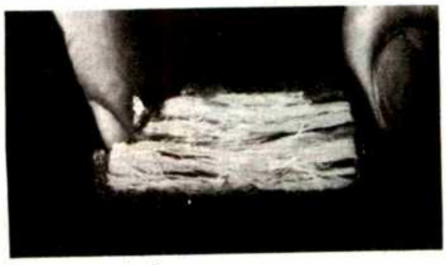
Ranks Hovis McDougall (RHM) have received qualified approval from the UK Ministry of Agriculture Fisheries and Food (MAFF) to market, for human consumption, the somewhat processed mycelia of a *Fusarium* fungus. The company has now taken the decision in principle to test whether there is a sufficient market to make a commercial success of the processed mycelia, which goes by the name of mycoprotein.

A pilot plant at RHM Research in High Wycombe, Buckinghamshire, has already produced up to 100 tons per annum of the processed mycelia, sufficient to carry out extensive toxicological and nutritional tests. These have shown that mycoprotein can be fed without ill effects to generations of laboratory animals. It has also passed a number of short-term tests on human volunteers. In nutritional terms mycoprotein compares well with meat, for which it might be a substitute. On a dry weight basis it contains 45 per cent protein — with an acceptable amino acid composition — and has a low fat (10–15 per cent, mostly unsaturated) and cholesterol content. There is also no doubt that it can be made palatable. The only questions now are whether or not its high fibre content (20–25 per cent) is as beneficial as current advocates of fibre would have it, and whether it will meet consumer resistance.

The fungus from which mycoprotein is produced is the A35 strain of *Fusarium graminearum*, a strain which has lost the pathogenicity to plants possessed by its relatives. It is grown in continuous culture at 30°C in 1,300-litre tanks with glucose-syrup as the carbon source and ammonia as the source of nitrogen. A key process follows in which the mycelia are immediately heated up to 64°C for 20 minutes. That treatment kills the mycelia, inactivates their proteolytic enzymes, so that there is no breakdown of protein, but allows the fungal ribonucleases to degrade nucleic acids into products which can be washed out of the cells. In that way the nucleic acid content of the mycelia is reduced from 10 per cent to below the acceptable upper limit of 1 per cent.



Fusarium mycelia before



...... and after

Furthermore the rapid heat treatment of the mycelia serves to reduce turgor with the result that mycoprotein has a texture that is not dissimilar to meat fibre. With the addition of flavouring and colouring, it can be made into a passable imitation of fish, chicken, veal or ham. Without any additions it is an unpalatable, colourless, tasteless product.

Human trials of mycoprotein have been very limited so far. Two small-scale and short-term nutritional studies have been carried out by Professor N. S. Scrimshaw at the Massachusetts Institute of Technology and some larger but less rigorous tests have been completed by RHM. The only problem that has emerged is a single case of an allergic reaction to mycoprotein which RHM claim is about par for the course.

On the basis of the human and animal tests MAFF has given permission to RHM to market mycoprotein on a limited scale once a specification has been agreed upon. It has also asked for further animal work to assess the effects of mycoprotein on mineral balance. There are two concerns in that respect. The first is that mycoprotein is lacking in the minerals, particularly iron and zinc, contained in meat. And the second is that the high fibre content of mycoprotein will lead to the retention in the intestine of dietary minerals from other sources — hence a recent recommendation that soya protein for human consumption be fortified with iron

Mycoprotein is the first of its kind. Several other microorganisms are grown and processed world-wide to provide protein supplements to animal feed, but none for human consumption. Also, as Dr J. Edelman, Director of Research at RHM, is at pains to point out, most of the animal feed supplements are the product of bacteria growing on hydrocarbons, and hence classifiable as single cell protein, whereas mycoprotein is produced by a multicellular fungus growing on glucose.

The main question mark still hanging over the future of mycoprotein is whether or not the public will buy it. When the project was started RHM had their eye on the protein gap that was believed to exist in many developing countries. That gap has since been declared a myth. Consequently RHM now have their eye on the UK convenience-food market (plans to seek approval for sale in the US have been put on ice because of the attitude of the Food and Drug Administration). To break into that market with mycoprotein will be no easy matter. Psychological barriers to new foods may be surmountable if the price is right but mycoprotein can only be cheap if produced in large enough quantity. Ten thousand tons per annum (0.25 per cent of annual UK meat consumption) would be realistic for that purpose, claims Dr Edelman; one hundred thousand tons would be "a bonanza" for the "nylon of the food trade".

Peter Newmark

Culture collections

Fears for fungi

The effectiveness of Britain's main collection of non-pathogenic microfungi could be seriously reduced from March next year if £20,000 annual support cannot be found in the meantime. The collection is currently funded to the tune of approximately £60,000 per annum by the Commonwealth Mycological Institute (CMI), which houses it, and £20,000 by the Natural Environment Research Council (NERC), which has said that it will cease to pay its share early next year.

Similar problems were experienced earlier this year by the National Collection of Yeast Cultures (see *Nature*, 24 January), as a result of which an inter-Research Council committee was set up with the aim of observing and monitoring the maintenance of culture collections. The problems of the microfungi collection are the first to be investigated by the new committee. Next week, members of the committee will visit the CMI to make detailed recommendations on how the collection should be continued and whether alternative funds are needed. It will then start looking for new sources of money.

The difficulties with both the yeast and microfungi collections have arisen because they have never been permanently funded. NERC took over the bill for the microfungi collection ten years ago from the then Ministry of Trade and Industry on a temporary basis. The grant was designed to rise with inflation up to a ceiling of £20,000, a level that was reached several years ago. According to the curator of the microfungi collection, Dr Agnes Onions, the collection is already run on a shoestring and if the NERC funds are not replaced it will be impossible to fulfull all the functions of a national collection.

The collection is the main source of non-pathogenic microfungi in Britain for industry, research and educational establishments.

Active experiments in space plasmas

From Michael J. Rycroft

SPACE physicists have in recent years been able to plan and conduct 'controlled' experiments in the ionospheric and magnetospheric plasmas. In the experiments, the medium near the space vehicle is deliberately perturbed by the injection of a signal of known characteristics. The signal may be in the form of energetic charged particles; for example, electrons with a particular energy, power and pulse duration injected with an electron gun. Alternatively, the signal may be in the form of electromagnetic waves; an example is the transmitter at Siple Station, Antarctica, injecting VLF waves of known frequency, amplitude and duration. The propagation of the signals can be detected enabling the medium remote from the space vehicle to be investigated.

As a recent conference* showed, the situation is not always as simple as that initially conceived by the experimenters. Soviet Zarnitza and Franco-Soviet Araks experiments of 1975 and recent US and Canadian experiments show that the operation of a high power electron gun aboard a rocket in the upper atmosphere causes complex processes to occur. A Beam Plasma Discharge (BDP) is often initiated; in this, the electron beam develops an instability in which ionospheric electrons are accelerated by plasma (Langmuir) oscillations. If heating to energies > 15 eV occurs, collisions with neutral molecules produce secondary electrons. If the neutral gas density, including the local increase due to outgassing from the rocket body, is high enough, this process cascades. Then a hot plasma halo is formed around the rocket; this is cigar-shaped and aligned along the geomagnetic field. Detectable by a low light level television system, the halo can have a luminosity equivalent to that of a fifth magnitude star. By providing the neutralization current, the enhanced plasma density in this region prevents the rocket potential rising as high as might otherwise have been expected for large electron beam currents.

This halo region is a source of HF (up to ~ 50 MHz) radio waves, at $\sim 2 \times 10^{-20}$ $\mathrm{Wm^{-2}Hz^{-1}}$. These electromagnetic waves are believed to be produced by conversion from electrostatic waves at the large gradients of plasma density existing at the edges of this region. Swept frequency studies show that the radiation is generated preferentially at the electron cyclotron frequency and at the electron plasma frequency, and also at the upper hybrid resonance frequency which is their Pythagorean sum. Radar reflections from the region are also observed. Whistler mode radiation is detected, as are bursts of noise at the lower hybrid resonance frequency which is inversly proportional to the square root of the mean ionic mass of the plasma.

Recently, Norwegian groups have successfully used mother-daughter payloads, with a pulsed electron accelerator being mounted on the daughter and the mother bearing a number of diagnostic instruments. The dimensions of the heated region are found to be two electron Larmor radii across the geomagnetic field and several times that along it. Noise bursts are observed to be generated, not only near the lower hybrid resonance frequency but also at lower frequencies, when the rocket crosses an auroral flux tube in the presence of precipitating energetic electrons. The waves are believed to be produced locally in the region perturbed by the beam and the neutralizing return current. In this issue of *Nature* (p.15) Gough *et al.* present observations, associated with the operation of the electron gun, of 0.8–1.0 MHz electrostatic waves and 8-10 KeV auroral electrons bunched at the same frequency. Waves are excited by the beam when it is injected into the ionospheric plasma; these in turn bunch the electrons in the beam.

A new development is in the use of huge vacuum chambers, such as the 12 m by 26 m chamber at the NASA Johnson Space Center, for laboratory investigation of the behaviour of electron guns before launch. Television recordings show that for low gun currents, the emitted electrons follow helical paths in the magnetic field. As the gun current is increased, a Beam Plasma Discharge is suddenly ignited. This is seen as a spatially broad beam, having a wide distribution in energy and with considerable light output due to the increased plasma production rate. Radiation in the whistler mode and Bernstein modes is recorded, as is noise around the electron plasma frequency and the upper hybrid resonance frequency. Performing experiments related to space plasma physics in the laboratory is a very necessary adjunct to performing laboratory-type active experiments in space plasmas.

Operation of a caesium plasma generator simultaneously with the electron gun in the Araks experiment caused the upper frequency of the HF emissions to increase above 50 MHz. In the West German Project Porcupine, experiments have been carried out involving ~ 200 eV xenon plasma injection. The dynamics of the plasma jet and associated wave processes are studied using instruments on the main rocket and on sub-payloads ejected from it. Particularly interesting are plasma instabilities induced by the xenon injection; sometimes these manifest themselves as electrostatic wave bands whose frequency separation is the cyclotron frequency of protons, but sometimes it is half this frequency. These ion cyclotron harmonic waves, which are detected both as AC electric field and plasma density perturbations, extend in frequency up to at least the twentieth harmonic. The most intense signals are located close to the estimated lower hybrid resonance frequency; of course, this frequency is changed considerably by the ion injection.

With shaped-charge explosive devices aboard rockets, barium has been injected upwards at high velocity. After ionization by solar ultra-violet radiation, the ions move up the geomagnetic flux tubes. Using sensitive optical equipment on the ground, upwards acceleration has sometimes been observed to occur at a height of a few thousand km, presumably by the action of an electric field. Such an electric field would accelerate auroral electrons

---

*A symposium on 'Active experiments in Space Plasmas' was held in Budapest from 11 to 13 June, 1980 as part of the 23rd meeting of COSPAR (the Committee on Space Research) established by the ICSU in 1958. Most of the invited review and contributed papers presented at the Symposium are to be published early in 1981 by Pergamon Press as a volume in the COSPAR Advances in Space Exploration series.

Michael J. Rycroft is Head of the Atmospheric Sciences Division, British Antarctic Survey, Natural Environment Research Council, Cambridge and was a member of the Symposium's Organising committee.

0028-0836/80/360007-02$01.00

downwards.

Project Trigger was a Swedish and US experiment designed to test the response of the auroral ionosphere to the explosive release of a hot, dense caesium plasma. A transient electric field is observed, as are variations of the field aligned fluxes of charged particles from 10 eV to > 300 keV. It is concluded that the field-aligned currents associated with the electric field pulse and cloud conductivity gradient may be responsible for the observed electron acceleration in a manner similar to that leading to the formation of auroral arcs.

Disturbances to the ionosphere are also caused by the explosive release of water from rockets. The ionospheric electrons rapidly recombine, leaving a 'hole' in the ionosphere. Simultaneously the flux of primary auroral electrons decreases by two orders of magnitude, probably because of changes in the auroral 'circuit' caused by the local conductivity decrease. Similar holes in the ionosphere are introduced inadvertently by the highly reactive exhaust gases from rocket engines. The Saturn V vehicle, which launched Skylab in 1973, caused the ionospheric electron content to be halved. The launch, in 1979, of the HEAO-C satellite by an Atlas/Centuar rocket provided confirmation of the effect. The ionosphere was significantly depleted over a horizontal distance of 300 km for some hours.

Ion engine thrusters are now being developed. Using these, ions will be injected into the magnetosphere in the form of a dense, relatively cool plasma beam with a high drift speed. Their effects have not been thoroughly investigated, either observationally or theoretically. Such work is essential because, for example, plans are being made in the US to transfer a Solar Power Satellite, of ~ 10^7 kg, from low earth orbit to geosynchronous orbit using argon ion thrusters. This would deposit ~ 10^6 kg of 3.5 keV argon ions into the magnetosphere. The ~ 10^{31} argon ions would equal the natural content of the magnetosphere, but their energy content would be about a thousand times larger than that present naturally. Such plans are therefore of considerable concern to magnetospheric physicists. It is desirable that preliminary experiments using ion thrusters in the magnetosphere be carried out as soon as possible.

A complementary type of active experiment is the injection of waves into the ionospheric or maganetospheric plasma. Since the launching of the Canadian top-side sounder satellites in 1962, plasma resonances have been stimulated by antennas within the natural space plasma. However, only since 1977, with the advent of the pairs of GEOS and ISEE satellites, and with the Japanese Jikiken (EXOS-B) satellite, have such resonances been studied in the magnetosphere and solar wind. Plasma frequency and upper hybrid resonance frequency signals enable plasmaspheric electron density profiles to be derived; some of these clearly exhibit the plasmapause with attendant fine structure. Bernstein mode electrostatic resonances, the so-called f_{Qn} resonances, plus resonances at harmonics of the electron cyclotron frequency are also observed. The effects of the drifting plasma and of its non-Maxwellian distribution have to be taken into account when interpreting these signals.

In recent years, controlled experiments on the magnetosphere have been carried out using coherent VLF electromagnetic waves injected from Siple Station, Antarctica which are ducted in the whistler mode from one hemisphere to the other. When radiating above a certain power <1W–2kW), these signals exhibit growth rates ranging from 30dB s^{-1}–200 dB s^{-1}. The energy source here is the cyclotron motion of the van Allen radiation belt electrons near the equatorial plane just inside the plasmapause; in the interaction the electrons' pitch angles are reduced and they can be precipitated into the upper atmosphere. The amplified signals can trigger emmisions whose frequency varies with time. Natural emissions are 'entrained', i.e. their frequency-time evolution is dramatically changed when their frequency comes within ~ 50 Hz of that of the coherent Siple signal. Sidebands, with growth evident only in the upper sideband, are generated. Growth of the Siple signals is suppressed either by a whistler mode echo of the signal or by a superposed broadband signal. Growth of natural noise is suppressed at frequencies just less than that of the Siple signal. Unducted signals from the Siple transmitter have been observed on the ISEE and Jikiken spacecraft.Triggering of emissions is evident when the satellite is in the magnetic Northern hemisphere, that is, after the Siple signal has crossed the equatorial plane of the plasmasphere. *In situ* wave-particle interaction studies now become possible, an exciting prospect indeed.

Radiation at harmonics of the fundamental frequency of the electrical power distribution (grid) systems of the industrialised world similarly penetrates the ionosphere and propagates in the whistler mode through the magnetosphere plasma. In principle it can interact with energetic electrons in much the same way as do the Siple signals. There is considerable evidence that it does in fact do so, though more observational studies are required. The significance of this 'pollution' of the magnetosphere remains to be quantified.

There is some controversy too as to whether the occurrence of chorus is affected by power line harmonic radiation. However, studies at Halley, Antarctica, which is geomagnetically conjugate to Newfoundland where there is a mixed 50 and60 Hz power system, show that the intensity of noise of magnetospheric origin at 3.2 kHz is, on average, 0.7 dB less on Sundays than on other days of the week. In a similar vein, but at very much lower frequencies, there is evidence from a century of data that geomagnetic activity is larger, by one standard deviation, at the weekends than during the week. Recent evidence shows that 1 pc pulsations of the geomagnetic field decrease when the DC operated San Francisco Bay Area Rapid Transit train system is operating. Could it be that the growth of ULF coherent waves, by a cyclotron resonance interaction with ions in the magnetosphere, is inhibited by ULF noise of man-made origin?

An HF transmitter, with an effective radiated power > 100 MW, has recently been constructed in northern Norway by West Germany. This powerful heater of the overhead ionosphere can modulate the temperature, and hence the conductivity, of the auroral ionosphere at frequencies between 0.2 and 5 kHz. In the presence of the auroral E-region electrojet, a signal at the frequency of the modulation is radiated. Signals with the appropriate whistler mode dispersion are recorded on the ground. A basically similar phenomenon, but with heating signals propagating obliquely from LF or MF Soviet transmitters, is responsible for the demodulation and radiation of 1 kHz timing pips, which can be received on the ground. More controlled experiments are required in this new field.

The present decade will see the first experiments carried out aboard Spacelab, to be launched by the Space Shuttle. The field of active experiments in space plasmas is well represented here. For example, Canada is proposing an MF/HF transmitter/receiver, with 0.5 kW peak power, using a dipole antenna of up to 300 m length tip-to-tip. Studies are planned of the transmitting antenna itself, ionospheric soundings, electromagnetic and electrostatic wave propagation in magnetoplasmas, parametric decay and plasma instabilities and nonlinearities. VLF wave injection is also proposed using the same antenna, the size being comparable with the whistler wavelength in the ionospheric medium. Waves can thus be injected over a range of wave normal angles (to the geomagnetic field) that are inaccesible from ground-based transmitters. The aim of such experiments is an increased understanding and control of magnetospheric wave-particle interaction mechanisms. Chemical releases, including water produced by fuel cells, from the shuttle are also planned. Finally, on the first Spacelab now scheduled for launch in 1983, Japanese, US and European groups are collaborating on intense (maximum 7.5 kV, 1.6A) electron injection experiments. These are designed to excite artificial aurorae, to study beam-plasma interactions in the ionosphere and to study charging of the Space Shuttle by operation of the gun and its neutralization by both plasma arcjets and neutral nitrogen plumes.□

100 years ago

A balloon ascent was made at Cherbourg, on the occasion of the *féte* given by the Municipality to M. Grévy, by MM. Perr and Capt. Gauthier. The general direction of the wind being from the land to the sea, a government steamer was sent out to secure the safety of the aëronants if necessary. Before starting not less than thirty pilot-balloons were sent up to ascertain the superposition of the aerial currents. It was proved that at 40 metres the wind was blowing from the sea. After having travelled for more than an hour in the direction of Portsmouth the aëronauts opened their valve and returned safely on shore. More than a hundred thousand spectators witnessed the experiment. The culminating point of the ascent was an altitude of 1,500 metres, where the travellers could see the English coast, the whole of the Isle of Wight, &c. The scenery is stated to have surpassed description. Some very curious observations were made on the colours of the sea. In the places where the water is very deep it looks quite inky, and the curves of level are so clearly manifested that they bear comparison with equidistance lines worked on ordnance maps. When travelling at so great an altitude ships can be detected with some difficulty; but smoke can be seen even when the smoke-producing steamer can hardly be perceived with the naked eye.

On the evening of July 20, about half-past eight o'clock a remarkable meteor, said to have resembled a comet, apparently about twenty yards in length was observed at Vizimgaum and other places in India, traversing the sky from south to north, and remaining visible for about three-quarters of a minute, during which time the whole sky and country were brilliantly illuminated. The meteor then burst, and some time afterwards a loud sound like distant thunder, which lasted two minutes, was heard.

At a concert given every night in the garden of the Palais Royale, Paris, the orchestra is placed in the vicinity of the fountains which are illuminated by eight splendid Siemens lamps, which work admirably. Two other Siemens lamps have been placed in the shop of a jeweller in the Galleries, and the experiment may eventually lead to the lighting of the whole palace by the electric light.

Maverick mitochondria

from a correspondent

LAST November, readers of these columns will recollect, the news broke that the genetic code, hitherto thought to be universal, was different in mitochondria. Now, new and startling revelations concerning the machinery that mitochondria use to translate the genetic code are described in three recent papers (*Proc. natn. Acad. Sci. U.S.A.* 77, 1980).

Mitochondria are organelles which exist inside eukaryotic cells where they perform the rites of oxidative phosphorylation. They possess their own DNA which contains genes for the enzymes they require for these rites as well as for their own ribosomal RNA and tRNA. To grasp the importance of the new findings we must first note that the 64 possible codons may be arranged in 16 families. Each family is defined by the first two bases of its codons so that, for instance, GU*N*, where *N* can be U,C,A or G defines the codons of the GU family. It is convenient to refer to the two codons of a family with a pyrimidine (U or C) in the third or 'wobble' position as the prymidine codons and the other two with A or G as the purine codons. In the standard genetic code, eight of the 16 families are unmixed: that is say all four codons in one family code for the same amino acid. In the mixed families several patterns of assignment exist; in six of them the pyrimidine codons signal one amino acid and the purine codons another or, in one family act as termination signals.

In the standard translational machinery, the codons interact one after another with tRNA molecules each bearing an appropriate amino acid. Each tRNA molecule has an anticodon of three bases that interact in an anti-parallel manner with the codon forming three base pairs. The first two base pairings are of the standard Watson-Crick type but the third in the wobble position may be more variable. In this way an anticodon may read from one to three different codons of the same family according to the nature of the base in its wobble position. For instance,an anticodon with U in the wobble position may read both purine codons of a family and one with G may read both pyrimidine codons. With the rules of wobble pairing in mind, it can be shown that a minimum of 31 types of tRNA are required to read the standard genetic code.

The three new papers first of all extend and consolidate our knowledge of the deviations from the standard code that occur in mitochondria from *Neurospera crassa.* (Heckman *et al. Proc. natn. Acad. Sci. U.S.A.* 77, 3159; 1980), from mammals (Barrell *et al. Proc. natn. Acad. Sci. U.S.A.* 77, 3164; 1980) and from yeast (Bonitz *et al. Proc. natn. Acad. Sci. U.S.A.* 77, 3167; 1980). In mitochondria from all three species it now transpires that UGA, instead of acting as a termination signal, codes for tryptophan as does the other purine codon from the UG family. In the AU family the code differs from standard only in mammalian mitochondria where the pyrimidine codons signal isoleucine and the purine codons methionine. Yeast and *Neurospera* abide by the standard pattern in this family. A further change occurs in the unmixed CU family of yeast in which all four codons signal threonine instead of the standard leucine. Apart from these deviations, the other codon assignments in mammals and yeast appear to be standard except for a suggestion that certain codons, normally used for arginine and which have not been detected in portions of the genome translated into protein, may be used as termination signals. In *Neorospera* no further deviants have been detected but the data are still incomplete. It may be noted in summary that the codes used by these three species not only differ from the standard but also differ among themselves. How many other deviations will show up in mitochondria from other species remains to be seen.

These observations, interesting though they may be, do not constitute the major bombshell delivered by these papers. As portents have been seen for some time it is disturbing that nobody has been able to find a full complement of 31 tRNA species in mitochondria, particularly since it has been shown that no extra tRNA is imported from the cytoplasm, at any rate in mammals.

Barrell *et al.* have now shown, by sequencing virtually the entire mitochondrial genome, that there are indeed only 23 tRNA genes in HeLa cell mitochondria. Similarly Bonitz *et al.* have found only 24 in yeast. An examination of the putative anticodons of these genes allows each to be assigned to a codon family. When this is done it is seen that eight are assigned to unmixed families. Invariably in mammals and in 7 cases in yeast these anticodons have a putative U in the wobble position. Since most of the 32 codons involved appear to be used to code for the

0028-0836/80/360009-02$01.00

appropriate amino acid it would appear that in some way these tRNA species can read all four codons of their families by recognising the two non-wobble bases and ignoring the third — a mechanism that I will call super-wobble. This is clearly anomalous but reminiscent of Lagerkvist's two-out-of-three reading scheme (Lagerkvist *Proc. natn. Acad. Sci. U.S.A.* **75**, 2759; 1978). The plot thickens when it is seen that eight further putative anticodons with G in the wobble position must be assigned, one each, to the remaining mixed families and six with a putative U to families requiring them. This makes it possible to read the mixed families according to standard wobble mechanisms.

A grave anomaly remains however. If an anticodon with U in the wobble position is able to read all four codons of an unmixed family, oblivious of the wobble base in the codon, how is it that the anticodons with a U in the third position are able to confine their attentions to the purine codons in the mixed families? To put it another way: why does super-wobble only occur in the unmixed families?

A clue to the answer to this conundrum is to be found in the paper by Heckman *et al.* They show from determinations of the sequence of six tRNA species that the U in those anticodons which must not indulge in super-wobble are modified (precisely how is still unclear) whereas the U in those that may so indulge is not modified. Modification inhibits super-wobble it seems but it remains still to be seen how this is done. Maybe the small and specialised mitochondrial ribosomes play some role in arranging this distinction. Meanwhile two points should be noted: first, most cytoplasmic tRNA species with a U in the wobble position have it in a modified form and second, this clue to the mechanism of the distinction is based on work on *Neurospera*. We must await further developments to see if the U's in mitochondrial tRNA from yeast or mammals are appropriately modified. □

Probing the mysteries of seeds

from Daphne J. Osborne

SEEDS are remarkable things. Each is a precise package enclosing a dry, quiescent and differentiated embryo, with attendant food reserves. Add water and within minutes the seed can be activated to renewed metabolic growth.

Almost every aspect of seed physiology and biochemistry was covered in discussion at the recent International Seed Germination Conference*. Ecologists for example, were assessing germination opportunity by mathematical modelling to include climatic variables and competitive interactions. Dormancy and dispersal of seeds were considered as alternative winning stratagems, depending on the habitat. One interesting model was for 'small patch' survival. In many desert plants, anti-dispersal mechanisms (atelochory) are winners. Seeds are held within the dried up plant until the rains so ensuring that they germinate in already successfully colonized sites.

Although a seed is said to have germinated when the root protrudes, there is no good definition in biochemical terms. The start of DNA replication could be the biochemical marker since imbibed but dormant seeds, although maintaining a continuous metabolic turnover, neither grow nor replicate their DNA and germinating embryos seem not to replicate their DNA until the radicle protrudes.

The depth of dormancy of seeds at shedding depends upon complex combinations of temperature, water availability and photoperiod during seed formation. Some seeds develop what is called secondary dormancy. This can happen if they remain imbibed under conditions in which they will not germinate. Those with a phytochrome-controlled dormancy, broken by exposure to red light may pass into secondary dormancy that is then independent of phytochrome control but broken by chilling. Some weed seeds develop a phytochrome-dependent secondary dormancy when they fail to germinate through lack of oxygen. This may account for successive bursts of germination observed in the field.

The question "do endogenous hormones control dormancy?" was a major talking point. Attempts to relate dormancy directly to either effects of hormone application, or to the levels of endogenous hormones in the seed proved unrewarding. For example, no relationship was established between abscisic acid and secondary dormancy and little understanding emerged for a mechanistic role for abscisic acid from the new, detailed knowledge of its metabolism during seed development and germination. Nor did there appear to be any obvious differences in abscisic acid biochemistry of dormant and non-dormant embryos which might account for their differences in germination. However, added abscisic acid does repress germination, so a role for abscisic acid is not excluded, even though studies of levels and metabolic products seem unlikely to provide the clues. Compartmentation or availability of hormones during particular receptive stages in seed development or germination are more likely to determine their regulatory functions: the precise stage of receptivity presumably depending upon the presence of the appropriate receptor proteins rather than the hormone level.

While control mechanisms of dormancy prove elusive, the mobilization by the embryo of stored protein and carbohydrate reserves at germination are demonstrably under hormonal control from the developing axis.

On seed imbibition in peas and beans, amylolytic or proteolytic activity in the cotyledons with subsequent hydrolysis of stored starch and protein is induced by the presence of the embryo axis (the radicle) or by addition of cytokinins; end-product inhibition or high osmotic concentration in the cotyledon are apparently not the reason for suppression of these enzymes in the absence of the axis. In lettuce, which stores mainly oligomannans, the radicle appears to transmit a stimulus to endosperm cells to produce β-mannanase with further breakdown of the mannans by a β-mannosidase induced in the cotyledons; the whole representing a linked and presumed hormonally regulated sequence. In mung bean cotyledon cells an endopeptidase synthesised on endoplasmic reticulum is transferred to the storage protein bodies during germination; the ensuing hydrolysis of these proteins illustrates the autophagic nature of these bodies and the central role of endoplasmic reticulum in enzyme synthesis. The lighter buoyant density of endoplasmic reticulum of aleurone cells during gibberellin-induced α-amylase production is therefore of considerable interest.

The physical and metabolic effects of seed hydration at germination are critical to seedling establishment. Restraints on water flow to the seed are imposed by the hydraulic properties of the seed-bed and the water energy level of the seed. Again, mathematical modelling based on experimental assays under different water availabilities can now provide predictions of field performance. Saline conditions appear to cause greater reductions of shoot than root growth. Accumulation of abscisic acid in the stressed cotyledons followed by preferential transfer to the shoot may account for this.

Maintaining the water content at a critical level for some while during seed hydration can, however, lead to more uniform germination and convey a greater resistance to sub-optimal temperatures. This is achieved by pretreatments which include an osmoticum such as polyethyleneglycol in the ambient imbibition medium prior to sowing. Such seeds can then be dehydrated and stored before

*A Seminar on "Control Mechanisms of and during Seed Germination" sponsored by the Bat Sheva de Rothschild Foundation for the advancement of Science in Israel was held in the Hebrew University, Jerusalem, from March 16th to 29th. The proceedings will be published this year in Volume 28 of the Israel Journal of Botany.

0028-0836/80/360010-02$01.00

sowing. But improvement does not always result. Secondary dormancy occurs if phytochrome controlled seeds are osmotically treated in the dark and there is a critical stage during imbibition before which the germinating seed is tolerant to subsequent dehydration and beyond which, removal of water results in cell death.

Desiccation tolerance of seeds is still poorly understood. It starts during seed formation when synthetic events are shut down. Polysomes are dissociated to monosomes with run-off of mRNA. Within minutes of rehydration at germination, polysomes are re-assembled suggesting that early protein synthesis could be initially independent of new RNA synthesis. But embryogenesis and germination are linked to changing protein patterns and in cotton cotyledons the maternal, constitutive and abscisic acid-induced protein products can be distinguished as well as their associated and different abundancy classes of PolyA-rich RNA messages.

Ageing seeds in the dry state, apparently sustain increasing levels of single stranded breaks in nuclear DNA and an early desiccation-tolerant event at germination is the 'repair' of these lesions with likely restoration of genome fidelity. Such repair capability is important for proper seedling establishment for failure to repair may lead to impaired vigour and low levels of early protein synthesis.

None of the early events of germination are possible without an energy supply. ATP levels are barely detectable in dry seeds. ATP production from inosine mono-phosphate or through an phosphoenol pyruvate-pyruvatekinase generating system are possible but measurements of energy charge favour oxidative phosphorylation. Differing mitochondrial activities may indeed be another factor controlling rates of early protein synthesis.

This meeting identified many problems, exposing the present lack of biochemical understanding of how desiccated cells survive, what makes them dormant and what breaks their dormancy. When knowledge in these areas becomes as far advanced as our current information on the biochemical events of early germination then another seminar will certainly be warranted. □

Bahamian Atlantis reconsidered

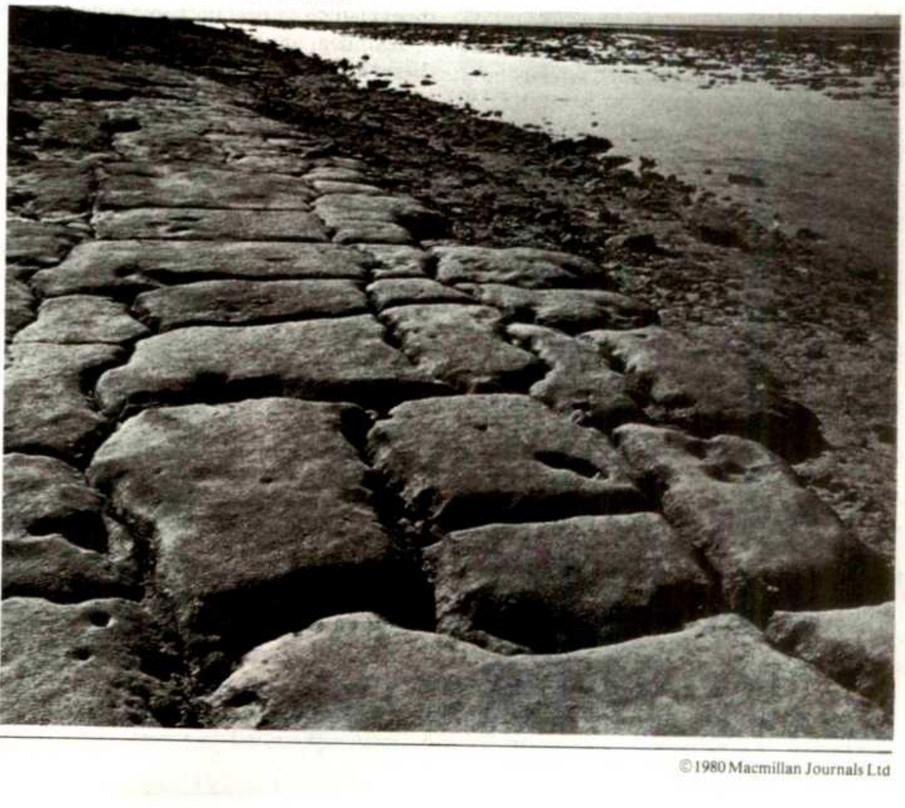
from Marshall McKusick and Eugene A. Shinn

During the late 1960s amateur explorers diving in shallow water found tabular limestone blocks which led them to repeatedly publish claims that Bimini Island in the Bahamas was the unsubmerged tip of the lost continent of Atlantis. In 1971, however, Harrison (*Nature* **230**, 287) argued that the supposed stone walls or roads were in fact natural limestone and that some submarine structures described as pillars were hardened concrete originally stored in wooden barrels and dumped overboard in recent times at the harbour entrance.[1] Nevertheless many amateur explorers have ignored the scientific explanation and books and articles that perpetuate this Atlantis myth continue to appear.[2,3] It is our contention that the persistence of the Bimini Island hoax must be explained in sociological rather than geological terms. There is in the US a vigorous cult dedicated to the mystic revelations of a native American prophet, Edgar Cayce (1877-1945), who wrote that lost Atlantis was the centre of all ancient civilization 10,000 years ago and that Bimini was part of that continent. Thus the Bimini affair has become a clash between scientific interpretation and religious dogma.

Geological studies have now gone beyond the 1971 geological reconnaissance of Harrison who wrote that a shell-hash gravel in shallow water was exposed and cemented during the most recent emergence of the Bahamian Banks. In 1978 Shinn's study reported that the so-called 'man-made roadway' was actually submerged beachrock.[4] On the Bimini beaches the high calcium content of the seawater allows the rapid formation of natural limestone beachrock — a fact demonstrated by glass shards, bottle caps, and other beach litter incorporated into the stone. Similar rapid formation of limestone has been shown in coral atolls in the Pacific where World WarII artefacts have been found in the matrix. Beachrock formed by the circulation and evaporation of calcium laden seawater has the following characteristics: (1) tabular fractures, (2) keystone vugs, (3) a surface slope and internal laminations which tend to parallel the beach incline, (4) stratigraphic continuation of sedimentary layers from one tabular block to another, and (5) an overall geometry which reflects tidal zone origin, that is, a narrow band frequently extending a mile or more along the sea front.

Amateur enthusiasts have claimed that the Bimini blocks were quarried by ancient Atlanteans and laid out in an ancient 'Cyclopean, megalithic roadway' which

Beachrock forming on Heron Island, Australia displays just the same features as the "Atlantis Road" in the Bahamas.



Marshall McKusick is Associate Professor of Anthropology, University of Iowa, Iowa City. Eugene Shinn is a member of the United States Geological Survey, Fisher Island Station, Miami Beach, Florida. His geological study at Bimini reported here was at his own expense and not part of any U.S.G.S. sponsored project.

0028-0836/80/360011-02$01.00

involved using squares and rectangles of various sizes including some 15 feet across. However the limestone structures observed off Bimini in 15 feet of sea have all the features of natural beachrock.[5] The limestone is in a narrow band overlying coral sand and extends for a considerable distance along a former shoreline. The so-called road's hairpin curve is not continuous and parallels the existing headland on shore. The tabular fractures are natural, and the original slope to the sea is present. A sample of 17 oriented cores obtained by Shinn and Tomkins has been examined with X-radiographs. Two areas of the formation were studied, and both show slope and uniform particle size, bedding planes and constant dip direction from one block to the next. If the stones had been quarried and relaid there is no reason to suppose bedding planes would carry stratigraphically from block to block. The sedimentary laminations clearly show that these were not randomly laid stones but a natural, relatively undisturbed formation.

Although under 15 feet of water, the beachrock is of recent geological origin. One ^{14}C date on shell has already been published as 2,200 ± 150 years BP. Jerry J. Stipp (Radiocarbon Dating Lab., University of Miami) has run seven bulk samples from the cores as a class project and gives slightly older dates for the Bimini submerged beachrock.

Laboratory Number	*^{14}C Years BP*
UM - 1363	2745 ± 80
UM - 1364	2770 ± 80
UM - 1359	2780 ± 65
UM - 1365	2835 ± 70
UM - 1361	3355 ± 90
UM - 1360	3500 ± 80
UM - 1362	3510 ± 65

Testing of submerged features in Florida and one test on North Bimini Island shows that the sea level has risen at a rate of about one inch every 40 years for the past 5,000 years. This rate of submergence over 2,200 to 3,500 years would account for 5.58 to 7.22 feet of the 15 feet of sea observed over the beachrock. The remaining 7 to 9 feet of sea may be explained by the undermining of sand allowing the beachrock to gradually settle, an erosive process that is seen in various stages in many parts of the Caribbean. Harrison's map shows that the submerged beachrock is located on the most exposed shore subjected to substantial erosion during winter storms.

The Bimini mystery has been used to promote tourism — "scuba dive over the lost road of Atlantis" — and has been exploited commercially in other ways. During the 1970's an enormous number of books describing ancient Atlantean, Phoenician, Egyptian, Viking, and other mysterious visitors to prehistoric America[6] have been published by both the major and minor New York commercial presses. This science fiction disguised as historical explanation is popular with the reading public and is part of a contempory fad. However, there is more to the Bimini-Atlantis hoax than commercialism. The mystic revelations of the American prophet Edgar Cayce have formed the basis of a successful religious cult with a national membership reported to be 18,000 and a staff of 110 at the Virginia Beach headquarters. The Cayce cult is a religion, and the revelations describe geological catastrophism as the explanation for Atlantis, the lost Pacific continent of Lemuria, and origin of civilization in such mythical lands. The 'sinking' of Atlantis according to Cayce's revelations occurred 10,000 years ago, although the radiocarbon dates of the natural formation show it originated some 7,000 years later.

To explain the rejection of archaeological and geological evidence, it must be said that Bimini is just one of a growing number of archaeological 'shrines' which have become the object of cult worship. Pyramid worship is becoming more common, and in England itself, mystic cults centre upon the alleged religious powers of Stonehenge and other megalithic monuments. Whatever the explanation of these new religious movements, they have led to an unfortunate rejection of the scientific explanation of natural and physical phenomena among a significant segment of the reading public. ☐

Retrograde transport in axons

from Peter Banks

A novel technique has been developed by Fink and Gainer[1,2] which makes it possible to follow the movements of proteins along nerve axons back towards the cell body. This retrograde movement is of physiological importance because it allows nerve growth factor (NGF) and possibly other materials released by innervated cells to reach the afferent cell bodies to modulate their metabolism. The retrograde axonal path is also taken by tetanus toxin and the neurotropic rabies and Herpes viruses; in the case of tetanus toxin, uptake by the nerve endings depends upon binding to specific sialogangliosides[3]. Recently, the exploitation of retrograde transport has provided an important new tool in neuroanatomical investigations. Horse-radish peroxidase (HRP) injected into the nerve endings can be followed back to the cell body allowing tracing of neuronal circuitry.

The mechanism of fast anterograde transport (50mm per day) from cell body to nerve ending is an energy-dependent process requiring Ca^{2+} ions, intact microtubules and actin[4]. However, the relationship between the smooth endoplasmic recticulum of the axon and neurotransmitter storage vesicles remains unknown. Retrograde transport is much less well understood but there is evidence, based on sensitivity to colchicine, for the involvement of microtubules. Under the electron microscope transported HRP is seen enclosed in membrane-bounded structures suggesting that the smooth endoplasmic reticulum provides the path for transport. However, in a reconstruction of serial sections of optic nerve[4], HRP previously injected into the contralateral optic tectum was never found in recognisable profiles of the reticulum even though, in ten instances, the latter's tortuous course was followed for over $4\mu m$. HRP was found in tubular and oval structures and in multivesicular bodies but none of those displayed any continuity with the endoplasmic reticulum.

Other than following the movement of HRP or of ^{125}I-labelled proteins taken up by nerve endings and direct light microscopy, there are few techniques for studying retrograde transport. Ligation techniques are of value for studying anterograde transport but not for retrograde transport. The distal segment of the nerve, in which retrograde movement towards the ligation is observed, begins to degenerate once contact is lost with the cell body and these changes occur first in the region of the ligation.

Fink and Gainer's new technique[3] enables axonal proteins to be labelled covalently with a radioactive marker (N-succinimidyl [2,3-^{3}H] propionate) following very localised injections into a nerve trunk. The subsequent retrograde and anterograde movements of the labelled proteins can be observed over extended periods of time. Although concentrating on slow transport (1 to 6mm/day), they also showed that the method should be applicable to the study of rapid transport, particularly in the neuro-hypophysial tract. Whilst the proteins transported

slowly in the centrifugal direction included the well-known cytoskeletal group, there was a single major centripetal species with a molecular weight of 68,000 which could be serum albumin or a fragment of the neurofilament protein.

The value of the HRP/retrograde transport technique has been greatly extended by some ingenious and very beautiful experiments performed at Oxford by Somogyi, Hodgson and Smith[5]. They combined the tracing of the source of afferent endings by HRP with a modified Golgi stain which enabled tham to identify the cell type acquiring HRP by its shape and dendritic arborization. By coupling the HRP injection with kainic acid, which destroys cell bodies with receptors for glutamic acid but not their afferent endings, and looking for degenerating boutons on the dendrites of Golgi stained cells which contain HRP, they were able to look for neural feed-back loops.

When they made an electrolytic lession in the striatum and injected HRP into the ventromedial nucleus of the thalamus, they found that the distal dendrites of Golgi stained/HRP positive cells in the pars reticularis of the substantia nigra carried degenerating synpatic boutons. They thus demonstrated that a three neurone circuit runs from the striatum and synapses in the substantia nigra and thalamus.

The capriciousness of the Golgi stain also allows the demonstration of stained interneurones synapsing with HRP positive cell bodies and, after placing appropriate lesions, there is also the possibility of detecting degenerating boutons on the interneurones. This multimethodological approach which combines light and electron microscopy, retrograde transport, Golgi staining and placement of lesions is potentially capable of answering many complex neuroanatomical questions.

The organization of efferent projections from the substantia nigra has also been investigated with the aid of the double retrograde fluorescent labelling technique by Kuypers and his colleagues in Rotterdam[6] who obtained evidence that some individual neurones projected to both the thalamus and tectum.

Axonal transport in all its manifestations continues to intrigue and occupy neurobiologists. It is perhaps unfortunate that knowledge concerning its mechanism has not yet matched the explosion of information gained from its exploitation.□

The acetylcholine receptor

from Charles F. Stevens

THE acetylcholine receptor (AcChR) has a a number of important firsts to its credit. As well as using the first neurotransmitter discovered, acetylcholine, it is the first protein of its class to have the conductance of a single open channel measured (25 pS) and to have the distribution of its pore 'open' times determined (the pore stays open an average of about 1 ms). The AcChR pore was also the first in a biological membrane to have the currents flowing through it measured directly (the single channel current is typically about 2.5 pA). Now this protein has chalked up another first: it has been reconstituted in an artificial planar lipid bilayer.

The acetylcholine receptor is very important because it is a representative of a large class of membrane proteins responsible for the electrical activity of the nervous system. These proteins respond to a signal, either a change in concentration of a neurotransmitter present at the membrane surface or a voltage change across the membrane containing the protein, by opening pores that permit ions to pass through the membrane; the ion flows then produce electrical signals which cause or modulate nerve impulse activity or, in the case of AcChR, lead through a chain of events to muscle contraction.

The AcChR is composed of 5 subunits, two smaller ones responsible for binding acetylcholine and three different larger ones whose function has not yet been established. The molecule spans the membrane, protruding about 5 nm from the outer membrane surface and 1.5 nm from the inner surface. Its diameter viewed face-on is about 8.5 nm with a 2.5 nm pit on the outer surface forming a vestibule which narrows to an 0.65 nm ion translocating pore.

A great deal of effort has been devoted to trying to get the isolated molecule to function in an artificial lipid bilayer. Techniques that had been successful in incorporating molecules such as the polypeptide antibiotic gramicidin and some larger but not well characterized molecules like excitability-inducing material into bilayers refused to work for the AcChR. Two technical innovations paved the way for the recent successes. First, Montal and Mueller (*Proc. natn. Acad. Sci. U.S.A.* **69**, 3561; 1972) reported a method of forming bilayers from two separately prepared lipid monolayers: lipid is spread at the interface between solution and air on two sides of a teflon partition that has a small hole in it. When the solution levels on both sides are raised above the hole, a lipid bilayer forms over it. Second, Schindler and Rosenbusch (*Proc. natn. Acad. Sci. U.S.A.* **75**, 3751; 1978) found that when vesicles containing membrane proteins are added to the solution below the monolayer, these vesicles establish an equilibrium with the surface monolayer so that some proteins in the vesicles enter the monolayer. When a bilayer is formed, proteins in the monolayer are then incorporated into the newly formed bilayer. Several methods are available for forming vesicles containing live AcChR molecules.

Two reports of successful reconstitution of the AcChR into bilayers using these techniques have just appeared. Schindler and Quast (*Proc. natn. Acad. Sci. U.S.A.* **77**, 3052; 1980) formed lipisomes containing receptor from *Torpedo* electroplax, the richest source of the AcChR. Nelson, Anholt, Lindstrom and Montal (*ibid* p. 3057) isolated and purified *Torpedo* AcChR, which was first reconstituted in soybean lipid vesicles using a technique developed by Epstein and Racker, and then incorporated the protein into lipid bilayers. The presence of functional AcChRs in the bilayer was detected by measuring an increase in the permeability to cations with applied acetylcholine and by showing that single pores had approximately the same conductance and mean open time as the native AcChR in its natural environment. Further, curare — an agent that is a competitive inhibitor of acetylcholine — blocked the effects of the natural agonist in the reconstituted system.

The next step will be to compare the properties of the reconstituted and native molecules. For example, a considerable change in protein dipole moment accompanies the conformational change at pore opening, and as a result the rates of opening and closing depend on the voltage across the membrane containing the AcChR. The effects of transmembrane voltage, as well as temperature and chemical structure of conformational change inducing ligand, will have to be investigated. Similarly, the alkali metal and alkaline earth cations, as well as a number of small (<.65 nm diameter) positively charged organic ions, pass through the open pore and the relative permeabilities of these ions will have to be determined for the reconstituted AcChR pore. Finally, the effects of the large number of pharmacological agents which alter the AcChR behavior will have to be investigated. In every case differences in the properties of the native and reconstituted molecules will need to be explained in terms of modifications that have occurred either during reconstitution or as result of the altered environment of the reconstituted molecule. When this is done, the advantages of having the reconstituted protein in an easily modifiable environment can be exploited.

As with other multimeric proteins the recently determined partial sequences for the four types of polypeptide chains

0028-0836/80/360013-02$01.00

constituting the AcChR show strong homologies, presumably because they evolved through gene duplication. (Raftery, Hunkapiller, Strader & Hood *Science* **208**, 1454; 1980). Many large proteins also have homologies within a peptide chain, again indicating tandem duplications of genetic material. The sequence known for the AcChR amounts to only about 10% of the total, too short to permit the detection of such homologies. However, additional parts of the sequence should be fairly easily obtained by the same techniques. Furthermore, because an estimated 2% of *Torpedo* electroplaque mRNA codes for AcChR, it should be possible to clone and sequence the genes. The base sequence will certainly be helpful in indicating the evolution of the molecule and will be a very important step toward relating the protein structure to its already well described function. The AcChR, then, has a number of chances to add still more firsts in the near future. □

Ultrasensitive mass spectrometry using accelerators

from K. W. Allen

THE detection of long lived radio isotopes such as ^{14}C by mass spectrometric methods using accelerators has a number of important advantages over more conventional methods based on observation of the emitted radiation. First, the sensitivity may be substantially increased, often by several orders of magnitude, so that measurements may be made using milligram samples in a reasonable length of time; second, through the use of a tandem accelerator in which fast negative ions are stripped within the high voltage terminal prior to the second stage of acceleration, discrimination against unwanted stable isobars (for example, N^{14} when detecting ^{14}C) and elimination of molecular ions (for example, ^{13}CH$^-$ which simulates ^{14}C$^-$) by dissociation in the stripper are achieved; and third, the relatively high final energy of the positive ions enables the well established techniques of nuclear particle identification to be employed to advantage.

Ultrasensitive mass spectrometry using the Berkeley 60″ cyclotron was first employed by Alvarez and Cornog in 1939 to show that He^3 rather than ^{3}H was stable, and later (1975) Alvarez and his associates used similar methods to set a very low limit for the natural occurrence of quarks. The need for more sensitive methods of ^{14}C dating in archaeology provided a strong impetus for new developments and in 1977 it was shown independently (see Müller *Physics Today* Feb. 23; 1979) that both cyclotrons and tandem Van de Graaff generators could be used successfully for ^{14}C dating. Within a year or two of these demonstration experiments, approval had been secured for the construction of 3MV tandem generators at the Universities of Arizona, Oxford and Toronto to be dedicated to ^{14}C dating and ultrasensitive mass spectrometry. The first of these new accelerators should be in operation by the end of 1980, but it is likely to be some time before the high accuracy in the ^{14}C/^{12}C isotopic ratio (<0.5%) essential for dating of archaeological samples is achieved on a routine basis.

The importance of accelerator based mass spectrometry increases as the lifetime of the radioisotope studied increases, since the specific activity decreases. Thus it is not surprising that accelerator based methods have already been applied to the detection of the long lived cosmogenic nuclides Be^{10} (1.62×10^6 y), Al^{26} (7.16×10^5 y) and Cl^{36} (3.00×10^5 y). The stable isobar at mass 26, Mg^{26}, does not appear to form negative ions so background is not a problem for Al^{26}. However since both Be^{10} and Cl^{36} have stable isobars, it is necessary to rely on chemical separation and specific ionization measurements to remove the background. At 20 MeV, S^{36} and Cl^{36} ions differ in their specific ionization by about 5%, but at $M = 100$, the difference for neighbouring isobars is only ~ 1%. Thus separation becomes increasingly difficult with increasing mass. In a recent article, Elmore *et al.* (*Nature* **286**, 138; 1980) have shown how a time of flight technique can be used to separate I^{129} (1.6×10^7 years) from I^{127}. Since there are many long lived radionuclides of astrophysical or cosmological interest with $A > 100$, this development is of considerable interest, not only because of the authors' success in measuring I^{129}/I^{127} in meteorites at the 5×10^{-12} level, but also because the experiments exposed the limitations of accelerators designed for nuclear physics research when used for ultra sensitive mass spectrometry of heavy elements.

The half life of I^{129}, although long in absolute terms, is short compared with the age of the solar system (4.55×10^9 years) so that all primordial I^{129} has long ago decayed to its stable daughter, Xe^{129}. There has been much analysis and speculation concerning the role of I^{129} decay in relation to the abundances of the Xenon isotopes in meteorites (see Drozd & Podosek *Earth planet. Sci. Lett.* **31**, 15; 1976) and the abundance of Xe^{129} in old tellurium bearing rocks has been used to set a lower limit of 1.6×10^{25} years to the lifetime of nucleon decay in Te^{130} (Evans & Steinberg *Science* **197**, 989; 1977. Since the decay of a proton or a neutron in Te^{130} leads to I^{129}, there would seem to be advantages in detecting I^{129} rather than its stable isobar Xe^{129} as the primordial background would then be eliminated. It should also be possible by accelerator based negative ion mass spectrometry to obtain greater sensitivity, by a factor $\sim 10^2$ to 10^3, than can be achieved by conventional means. Since the equilibrium yield of I^{129} from nucleon decay, assuming a half life of 10^{30} years, is at most $\sim$ 1300 I^{129} atoms per kilogram of tellurium, improved sensitivity would be very welcome! It will clearly be necessary to obtain tellurium samples from very deep mines to minimise the I^{129} background from radiative neutron capture in Te^{128}, (the neutrons coming from energetic muon interactions), but the occurence of tellurium in association with gold and silver, which both encourages mining and provides neutron shielding for the tellurium, is a helpful factor. While the sensitivity of geochemical methods such as that described above cannot approach that obtainable with the very large cerenkov detectors now under construction for those events in which the entire rest energy of the nucleon is liberated within the detector, the technique is independent of nucleon decay mode and could in principle detect events in which several neutrinos are emitted. Such events are most unlikely to be revealed by direct detection methods.

The detection of nucleon decay is probably the most challenging and difficult application for ultrasensitive mass spectrometry. There are, however, many fields where the technique is likely, after further development, to prove useful. The measurement of the terrestrial abundance of long lived radionuclides such as Pu^{244}, which has a bearing on the origin of the solar system (Hoffman *et al. Nature* **234**, 132; 1971), the detection of solar neutrinos, the search for superheavy elements and the detection of rare stable nuclides at a level of parts per billion are all possible areas of application. The recent work on I^{129} (Elmore *et al.* loc. cit.) emphasizes the value of time of flight techniques and the importance of good resolution at injection to eliminate undesirable negative ions; the heavier the ion, the more important these considerations will be.

It seems likely that, over the next few years, tandem generators which are now too small for effective nuclear physics research will be put to good use as ultrasensitive mass spectrometers. It will be necessary to install high resolution injectors on these accelerators, improve the vacuum systems, and perhaps develop new types of detector, especially for the heavier elements. These improvements are relatively modest however, and it should be possible for small groups working on their own University campuses to make important contributions in many different fields. □

Bunching of 8–10 keV auroral electrons near an artificial electron beam

M. P. Gough*, B. N. Maehlum†, G. Martelli*, P. N. Smith* & G. Ventura‡

*School of Mathematical and Physical Sciences, University of Sussex, Brighton BN1 9QH, UK
†Norwegian Defence Research Establishment, Kjeller, Norway
‡University of Florence, Florence, Italy

High frequency modulations (~1 MHz) of energetic (keV) electrons in the auroral ionosphere have been detected unambiguously for the first time using a novel technique. These modulations were induced by an artificially injected pulsed electron beam (8 keV, 4% duty cycle), and were accompanied by electrostatic wave emissions at the same frequency.

IF waves are excited by a charged beam in a magnetoactive plasma, the beam particles should become bunched at or near the frequency of the excited waves. This is also true for the auroral ionosphere, where such bunching effects could be a useful diagnostic technique. Hitherto these effects could not be studied because of the limited bandwidth of rocket telemetry systems. A technique which overcomes this problem was applied here to the semi-controlled conditions provided by a rocket borne 'mother–daughter' experiment incorporating an artificially injected electron beam.

Several experiments have been carried out with electron guns mounted on rocket payloads[1–3]. Emissions created by these electron beams are observed up to frequencies beyond the electron plasma frequency. Cartwright and Kellogg[4], however, noted that most of the radiated beam power goes into waves propagating below the local electron gyro-frequency f_{ce}(~1.4 MHz) as whistler mode waves.

More recently, similar emissions have been observed in natural auroras by receivers operated on the ground[5,6]. Kisabeth and Rostoker[6] further identify the source of the emissions below f_{ce} as field aligned currents with the highest frequencies below f_{ce} associated with electron beams in discrete auroral arcs.

We present here results from an artificial auroral beam experiment in which beam-induced bunching of the energetic auroral electrons is observed at a wave frequency of 0.7 f_{ce}. The only previous attempt[7] to detect bunching or modulation of auroral electrons up to megahertz frequencies yielded an ambiguously low level of modulation around the detection threshold of the instrument.

Observational technique

On 27 November 1978 at 18.55.35 UT, a Nike Tomahawk rocket (Electron 2) was launched from the Andoya Rocket Range, 69° 17′ N, 16° 01′ E, Northern Norway, during natural auroral activity. The main payload or 'mother' was instrumented to measure energetic particles, waves and ambient plasma while a separating sub-payload or 'daughter' contained an electron gun producing at peak current a 100 mA beam of 8-keV electrons. The daughter separated at 70 s (95-km altitude) with a relative forward velocity of 0.5 m before the gun pulse sequence started at 92 s and useful particle measurements were made on the mother between 80 s (108 km on the upleg) and 351 s (108 km on the downleg).

On the mother one of the electrostatic analysers was operated at fixed energy 8–10 keV with near omnidirectional opening angle of 190 × 5°, to monitor both the background and the gun electrons. The channeltron pulses from this detector were analysed as described below to investigate bunching up to frequencies of 5 MHz. Electrostatic and electromagnetic waves measured on the mother by a pair of boom-mounted electrostatic sensors connected to a receiver sweeping between 0.2 and 3.8 MHz (every 30 ms with a bandwidth of 100 kHz) were recorded simultaneously.

The megahertz bunching analysis of the detected 8-keV electrons was performed by on-board processing of the channeltron detector pulses described fully by Gough[8]. The time interval between subsequent pulses produced by 8 keV electrons was measured as the number of cycles of a 10 MHz crystal oscillator. If the electrons arrive randomly at an average rate C s^{-1}, then the probability $P(M)$ of two electrons arriving separated by M cycles of the 10-MHz clock will be given by

$$P(M) = P_0\, e^{-MP_0} \qquad (1)$$

where

$$P_0 = C/10^7 \ll 1$$

Any bunching of the electrons at frequency F (due, for example, to wave–particle interactions) should appear as a cyclic modulation with periodicity $10^7/F$ cycles superimposed on top of the normal non-bunched distribution given by equation (1).

The most probable measurements are those of the shortest time intervals separating two pulses. Given a sufficient accumulation time this makes the technique sensitive to frequencies orders of magnitude greater than the count-rate, but limited by the sampling theorem to a maximum frequency of one half of the crystal clock frequency.

In this preliminary experiment only the time interval between the last two electrons arriving before each telemetry readout was transmitted to the ground. Thus only 400 measurements were available each second, although the average electron arrival rate was between 5×10^3 and 5×10^4 s^{-1}.

If we call $N(M)$ the number of observed pairs of electrons separated by M clock cycles, any bunching at frequency F will produce in the array $N(M)$ maxima around $M = 0$, $M = 10^7/F$, $M = 2\times10^7/F$, and so on. Consequently each data set was searched for the presence of electron bunching at 140 frequency intervals spread linearly between 0.2 and 5 MHz. For each frequency trial, the distribution $N(M)$ was multiplied by a square wave of amplitude ±1 lasting four cycles with phase zero at $M = 0$ (the zero being corrected for electronics dead time).

In the absence of bunching, the distribution of the entries $N(0)$, $N(1)$, $N(2)$, and so on, are approximately poissonian and independent. The difference between the number of counts accumulated in the positive parts of the square wave over those in the negative parts divided by the square root of the total number of counts encompassed by the square wave is expressed as the ratio Z. A 'non-bunched' distribution would give $Z \sim 1$. It follows that the probability of a non-bunched distribution giving $Z > 3$ is 0.0014, and $Z > 2$ is 0.025, for each frequency trial.

0028–0836/80/360015—03$01.00

Experimental results

Figure 1 shows eight sequential data sets of 33.5 s (five spins of the rocket) analysed in the way described above, with Z plotted whenever it exceeded +1.0. The scale is linear and the $Z = +3$ level is given by the base line of the previous data set. This type of frequency analysis enables us to determine fundamental bunching frequencies, although spurious higher harmonics may also appear. The most striking feature of Fig. 1 is a peak which moves down from 1.0 MHz in the data set centred on 99 s to 0.8 MHz in the data set centred on 232 s. The fact that the spectral pattern repeats itself in five consecutive data sets is highly significant.

As in this frequency band the maximum values of Z are 3.5, 4.1, 2.5, 4.0 and 3.4 for the first five spectra respectively, the electrons can be said to have been definitely bunched in the 0.8–1.0 MHz range.

The electrostatic wave sensors on the mother payload were designed to measure waves in this frequency range. Wave bursts associated with the gun pulses were observed in the same narrow frequency band. Unfortunately the booms on which the sensors were mounted did not deploy fully and the data appear to be contaminated by interference, possibly generated within the payload.

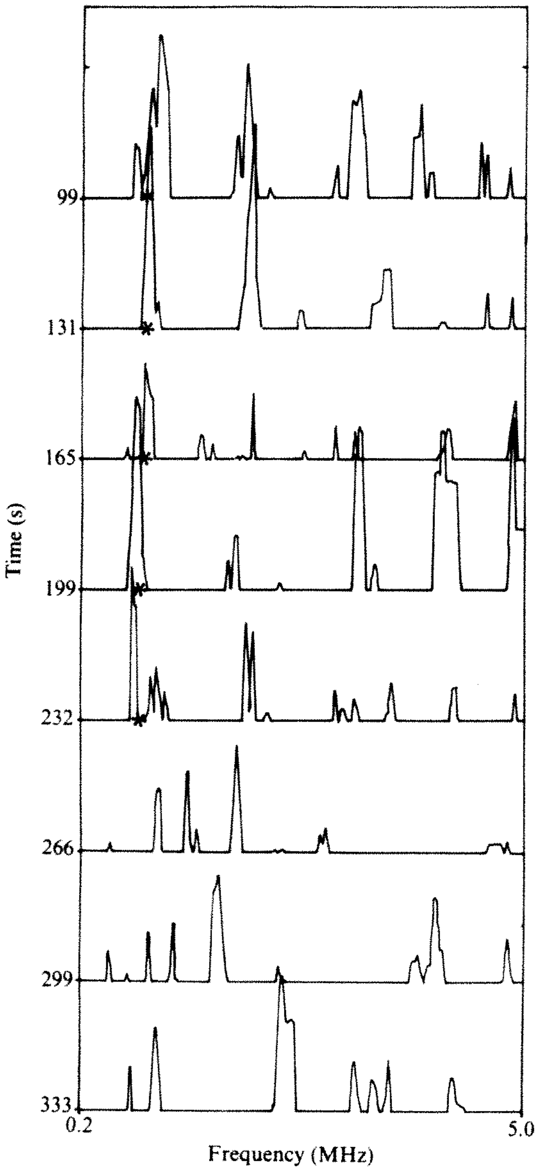

Fig. 1 The observed bunching frequencies of the 8-keV electrons. 33.5 s (five spins) groups of data are presented with Z (see text) plotted against frequency when above $Z = +1$ (baseline) where $Z = +3$ is the baseline of the previous data set.*, Position of the emission observed on the electric field booms. The frequency scale is linear from 200 kHz to 5 MHz.

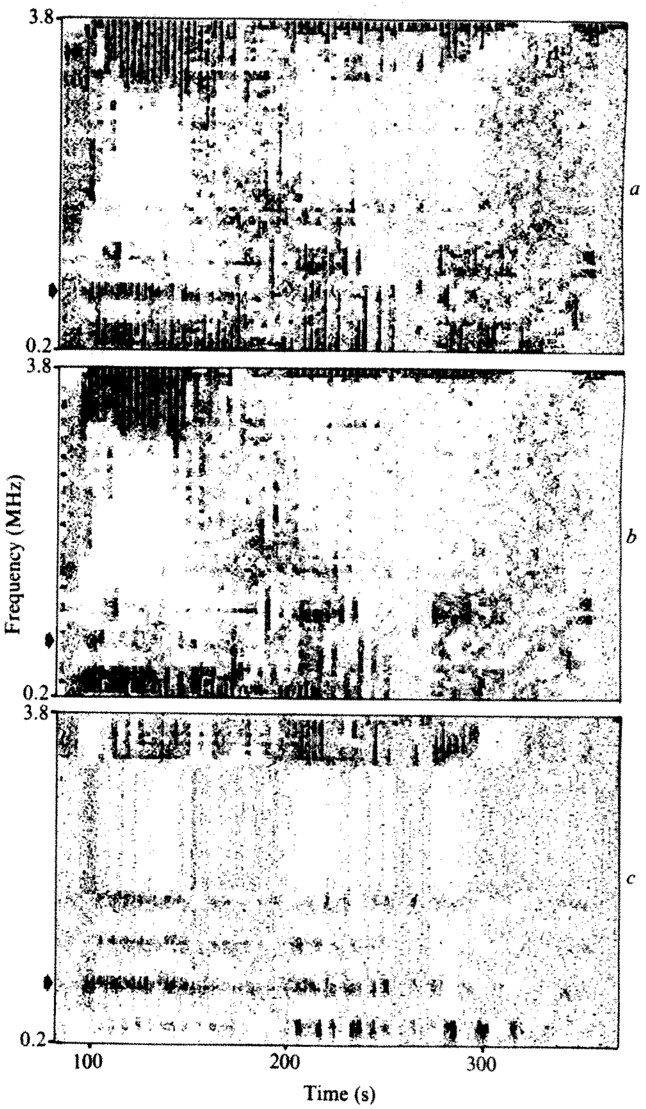

Fig. 2 3.4 s average spectra of electrostatic emissions observed by the electric boom-mounted sensors after subtraction of the average spectrum from 300 to 350 s to remove local interference signals. *a*, All data; *b*, data in between gun pulses; *c*, data during gun pulses. The arrow indicates the position of the emission at $0.7 f_{ce}$. The frequency scales are linear from 200 kHz to 3.8 MHz.

We can assume that towards the end of the flight, the effect of the gun electrons would be much reduced since the mother and daughter reach by then maximum separation, while the interference, if generated in the payload, should not change much. This allows us to correct for interference effects. Figure 2 shows grey scaled 3.4-s average spectra ($\frac{1}{2}$ spin) displayed after subtracting from them the average spectrum for the last part of the rocket flight (300–350 s).

Figure 2*a* shows all the wave data, Fig. 2*b* the wave data recorded in between gun pulses, and Fig. 2*c* the wave data during gun pulses. A distinctive feature of Fig. 2*a* is an emission in the band 0.8–1.0 MHz that persists from 95 s until ~260 s where it disappears in the noise. This emission is much reduced in Fig. 2*b* but enhanced in Fig. 2*c* to be the most distinctive feature in the spectrum. Clearly the emission is directly gun associated and decays rapidly at the end of a gun pulse. The average position of its peak during the 33.5-s data sets of the particle bunching is plotted on the base lines of Fig. 1 as a star for comparison. The close fit clearly shows that the frequency of the electron bunching coincides with that of the observed electrostatic wave. There is no conceivable way in which the two instruments could interfere with each other and we conclude the observed bunching effects are real.

Figure 2 shows clearly that the emission begins soon after 92 s, when the electron gun is switched on. A study of shorter 6.7-s (1 spin) data sets of the electron bunching indicates that no bunching occurred before this time. Similar data sets show that the electron bunching ceases between 250 and 260 s. At this time, the separation between the mother and daughter is ~40 m perpendicular to the geomagnetic field lines. A previous experiment carrying a similar electron gun[9] showed that at this separation the contribution to the observed fluxes by the gun electrons was vanishingly small.

The electron gun was pulsed every 163 ms with a pulse pattern lasting no more than 9.6 ms. The pulse pattern alternated between a single pulse of 9.6 ms, a single pulse of 0.96 ms or a group of six pulses each 1.9 ms. The electron bunching measurements were consequently sorted into three separate data sets for the period 80–260 s into the flight.

The first set contained all measurements made within 54 ms time bins centred on all electron gun pulses (of all three types), the second set corresponds to the next 54-ms time bins and the third set corresponds to the last 54-ms time bins before those containing the next gun pulse pattern. The values of Z of the peak observed around the 1-MHz frequency interval were 3.6, 2.9 and 1.9 respectively, thus showing that the bunching is directly related to the electron gun pulses. However, the measurements are carried out evenly in time but the duty cycle of the gun is much less than unity. Most of the recorded electrons are, therefore, of auroral origin with the observed bunching induced in them by the electron gun pulses.

Discussion

Typical electron plasma frequencies at this altitude are many megahertz, and we would expect to observe electron bunching around the electron plasma and upper hybrid frequencies. However, electron bunching and wave emission occurred at 0.8–1.0 MHz, that is around 0.7 of the local electron gyrofrequency f_{ce}. Several apparently significant peaks ($Z > 2$) occur above 1 MHz in the bunching spectra but, as mentioned above, we have ignored them as they may be spurious artefacts of the method of frequency analysis used here. We have, therefore, limited our discussion to the 0.9-MHz signal.

Jones and Kellogg[10] have provided the theory most relevant to the case of an artificial electron beam in the auroral ionosphere. Using beam-plasma parameters different from those in our case, they have shown that waves will grow in the electrostatic whistler mode but with a small growth rate. Results of calculations using parameters closer to those expected in our experiment show that the electrostatic whistler mode waves (or obliquely propagating electron plasma waves) are unstable in the region of 0.7 f_{ce} (V. K. Jain, personal communication). Maggs[11,12] has shown theoretically that natural electrostatic whistler noise undergoes convective beam amplification if there is a positive slope in the velocity distribution. Such a slope has been seen in natural auroral electron beams associated with waves of this type[6]. As noted above, the measured bunching occurred mainly in the natural auroral electrons, and this effect may have been enhanced or induced by the presence of the beam.

Bunching of naturally occurring intense auroral beams can also be expected, and this technique promises to be a valuable diagnostic tool in advancing our understanding of the processes involved in the aurora.

We thank B. Blackman for building the boom deployment system, B. Narheim for designing the omnidirectional counter, M. Moore and R. White for constructing the bunching electronics, Professor J. A. Bather for advice on statistical interpretation, Dr P. J. Christiansen and T. A. Jacobsen for helpful comments, and P. Rothwell for making available the video records of the aurora.

Nicholson's blowflies revisited

W. S. C. Gurney, S. P. Blythe & R. M. Nisbet

Department of Applied Physics, University of Strathclyde, Glasgow G4 0NG, UK

A simple time-delay model of laboratory insect populations which postulates a 'humped' relationship between future adult recruitment and current adult population gives good quantitative agreement with Nicholson's classic blowfly data and explains the appearance of narrow 'discrete' generations in cycling populations.

NUMEROUS elementary ecology texts use as illustrative examples of oscillatory population fluctuations, data drawn from the comprehensive and elegant experiments performed by Nicholson[1,2] on laboratory cultures of the sheep blowfly *Lucilia cuprina*; in these, the population was regulated by the rate of food supply to either the adult population (Fig. 1*a*) or the larval population (Fig. 1*b*, *c*). Notwithstanding their popularity as alleged examples of oscillatory behaviour, the large, quasi-periodic population fluctuations observed by Nicholson are still very imperfectly understood. It is clear from the work of Maynard Smith[3] and May[4] that a combination of high fertility and long development delay must be primarily responsible, and the discrete-time model developed by Varley, Gradwell and Hassell[5] further suggests that a degree of 'overcompensation' in the controlling density dependence may be important. However, beyond these rather generalized insights progress has been slight. Despite a variety of more or less sophisticated attempts[4–6], no theoretical model has yet yielded a truly satisfactory quantitative fit to the time history of even a single culture, still less has it been possible to formulate a comprehensive framework within which the various subtly different experimental results can be systematically inter-related.

In this article, we seek to formulate a model capable of providing such a framework, but as an initially less grandiose target we shall try to answer a number of specific questions about Nicholson's blowfly data. First, we must identify the class of mechanism which produces the quasi-periodic fluctuations; are they self-sustaining limit cycles perturbed by experimental

0028-0836/80/360017—05$01.00

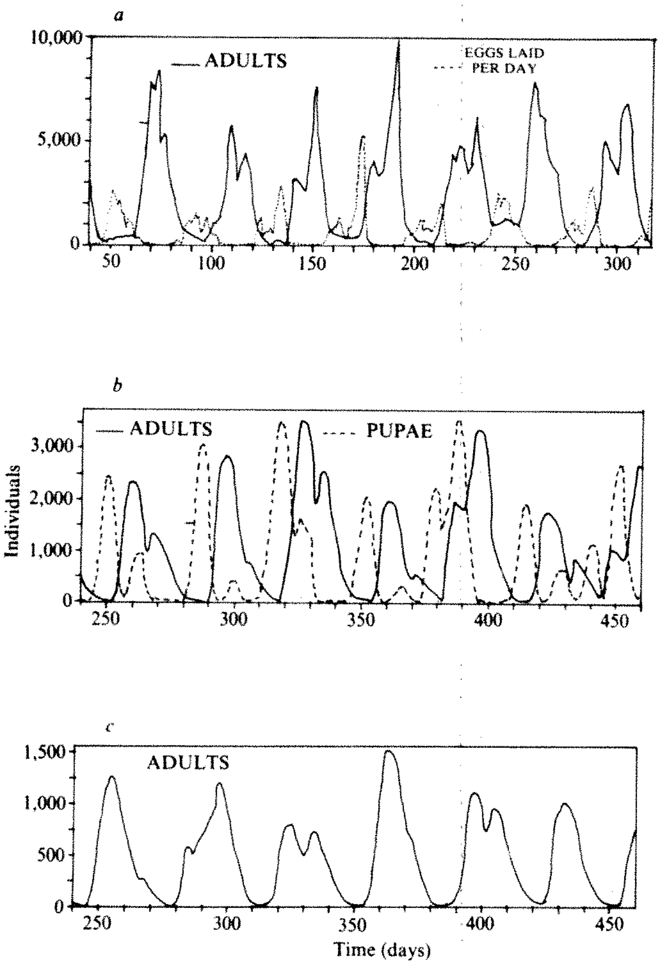

Fig. 1 Quasi-periodic fluctuations in laboratory populations of *Lucilia cuprina*. Population regulated by adult food supply (*a*), larval food supply (50 g per day) (*b*), larval food supply (25 g per day) (*c*). Data from ref. 1.

uncertainty and demographic stochasticity, or are they true quasi-cycles[7] driven by demographic or environmental stochasticity? Second, we wish to know what determines the period and amplitude of the cycles. Lastly and perhaps most interestingly, we wish to understand the observed patterns of breeding activity; specifically, why the two discrete generations per cycle observed in the larval food-limited case (Fig. 1*b*) occur at uneven time intervals, and why in the adult food-limited case (Fig. 1*a*) they merge into a single, almost continuous period of reproductive activity.

The time-delayed logistic model

If it is to be capable of answering questions about the form and timing of generations, our model clearly cannot simply assume that generations are discrete; rather, it must make the initial assumption of overlapping generations and its dynamics must be such as to cause the spontaneous appearance of clearly marked discrete generations in the appropriate conditions. This implies that it must be formulated in terms of a differential, rather than a difference, equation. Probably the simplest single-species continuous time model capable of generating cyclic or quasi-cyclic fluctuations is the time-delayed logistic

$$\frac{dN(t)}{dt} = rN\left[1 - \frac{N(t-T_D)}{K}\right] \qquad (1)$$

May[4] showed that this model gave an acceptable gross fit to the adult population data shown in Fig. 1*a* with a delay time T_D of about 9 days, a value which he argued compared acceptably with the observed delay time. However, there are several serious objections to the time-delayed logistic model both in general and as a specific explanation of Nicholson's data. First, close examination of the life history data[2] shows that the appropriate experimental value of T_D is 14.8 ± 0.4 days, which implies that the discrepancy between 'best fit' and experimental values is worryingly large compared with the confidence interval in the best fit value (±0.5 days). Second, the model "mixes up time-lagged and not time-lagged contributions" (R. M. May, personal communication) in a way which makes it a very poor paradigm for biological phenomena. However, even more serious than either of these objections is the fact that the time-delayed logistic model is entirely incapable of predicting two bursts of reproductive activity per adult population cycle. It is thus structurally incapable of explaining the results obtained by Nicholson in the larval food-limited regime.

A more realistic model

We now formulate an improved continuous time model of an insect population growing in an isolated laboratory culture. As the experimental data which will serve as the primary quantitative test of the model are mainly based on observations of adult population as a function of time, we begin by writing down a balance equation for the population of sexually mature adults, $N(t)$. The experimental conditions clearly preclude any immigration or emigration and thus the rate of change of N must simply be the difference between the total adult death rate (D) and the rate of recruitment to the adult population (R). If we assume that the *per capita* adult death rate has a time- and density-independent value δ, then

$$\frac{dN}{dt} = R - D = R - \delta N \qquad (2)$$

The adult recruitment rate, R, should be evaluated by writing down analogous balance equations for all the life history stages of the species concerned. However, we can evade the resulting complexity (and increase the generality of our model) with the aid of three simplifying assumptions: (1) the rate at which eggs are produced depends only on the current size of the adult population; (2) all eggs which develop into sexually mature adults take exactly T_D time units to do so; (3) the probability of a given egg maturing into a viable adult depends only on the number of competitors of the same age. Together, these assumptions imply that the rate of recruitment at time t can only be a function of the size of the adult population at time $t - T_D$

$$R = R(N(t - T_D)) \qquad (3)$$

so that the entire population dynamic can be expressed by a single delay-differential equation

$$\frac{dN}{dt} = R(N(t - T_D)) - \delta N(t) \qquad (4)$$

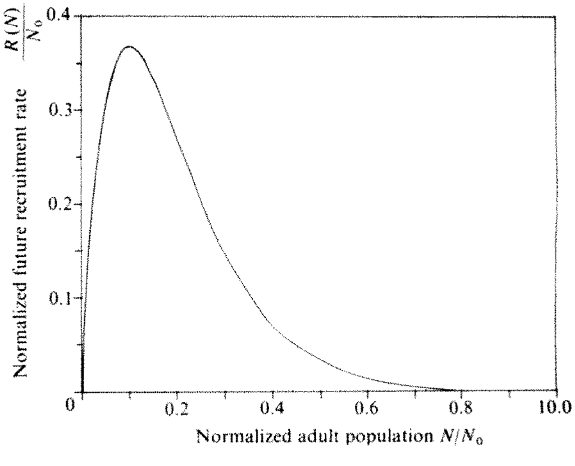

Fig. 2 Assumed dependence of future recruitment rate against present adult population.

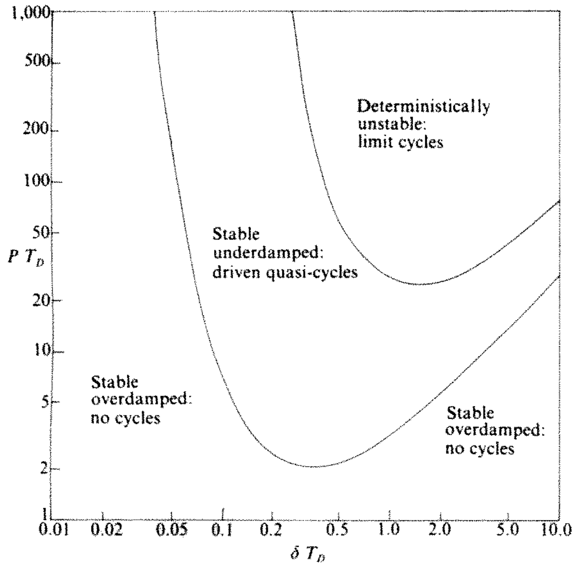

Fig. 3 Qualitative behaviour of the model as a function of the controlling parameters PT_D and δT_D.

Although the recruitment rate function $R(N)$ can in principle be subject to experimental measurement, we wish our model to act as a paradigm for a rather larger class of similar models as well as provide a detailed fit to Nicholson's data, and we therefore seek rather to write down an appropriate algebraic form for $R(N)$. We consider first those experiments in which the only limiting factor is the rate at which food is supplied to the adult population. Here, egg to adult survival may reasonably be expected to be density independent, so that the rate of adult recruitment at time t will be directly proportional to the rate at which eggs were being laid at time $t-T_D$. Provided that the population sex ratio remains reasonably constant, it seems plausible to suppose that, in the presence of excess food, the total rate at which eggs are produced by a population of N adults will be directly proportional to N. However, when food is supplied at a limited rate, intraspecific competition will clearly act to reduce the average *per capita* fecundity of the members of large populations to well below its physiological saturation value. Indeed, where competition is of the 'scramble' type[1], it seems highly likely that very large populations will require the whole of their restricted food intake for physiological maintenance and will thus produce no offspring at all. Clear experimental evidence of such an effect can be found in Fig. 1*a*, which shows that in Nicholson's adult food-limited culture the total egg production rate drops to zero at high populations. Any plausible functional form for $R(N)$ must therefore go to zero as N becomes either very large or very small. In addition, it seems likely that most recruitment curves will display a single maximum (see Fig. 2) at an intermediate population whose size is determined by the available resources. We therefore choose to represent $R(N)$ by a simple function which displays all these properties

$$R(N) = PN \exp\{-N/N_0\} \qquad (5)$$

where P is the maximum possible *per capita* egg production rate (corrected for egg to adult survival) and N_0 is the population size at which the population as a whole achieves maximum reproductive success.

In experiments in which the controlling factor is the rate of food supply to the larval population, the situation is at first sight entirely different. Here, the adults are always provided with excess food and thus always produce eggs at their physiological maximum rate. However, competition among the larvae now makes egg to adult survival highly density dependent, and indeed, Nicholson's batch culture experiments strongly suggest that when an age class is very large, none of its members will actually pupate successfully. Thus, within the limitations of our assumption that egg to adult survival is affected only by competition within a given age class, we can use equation (5) to describe recruitment in both the adult food-limited and the larval food-limited cases.

The dynamics of our model are thus always described by

$$\frac{dN(t)}{dt} = PN(t-T_D)\exp\{-N(t-T_D)/N_D\} - \delta N(t) \qquad (6)$$

which has a single non-trivial stationary state

$$N^* = N_D \ln(P/\delta) \qquad (7)$$

It can easily be shown that the local stability of the steady state and the qualitative properties of the fluctuations about it are entirely controlled by the two quantities PT_D and δT_D, and in Fig. 3 we show the disposition in the $PT_D/\delta T_D$ plane of the various regions of qualitatively different behaviour. Because we seek to understand fluctuations which are at least quasi-periodic, we shall restrict our detailed analysis to the stable/underdamped (damped oscillatory) and locally unstable regions.

If the parameters of our deterministic model are in the stable/underdamped region, we would expect the demographic stochasticity present in a real system to induce quasi-cyclic population fluctuations consisting of bursts of relatively coherent cycles whose period is close to the deterministic natural period, interspersed with short periods of incoherent noise[7]. If we describe the return of an underdamped system to its deterministic equilibrium by a coherence number n_c, defined as the number of cycles over which the amplitude of the transient is reduced by a factor e, then it is found empirically[8] that when such a system is executing driven quasi-cycles, each burst of coherent cycles contains an average of roughly $3n_c$ cycles. Thus, in Fig. 4 we characterize the quasi-cyclic behaviour of our model in the stable/underdamped regime by plotting contours of constant normalized cycle period (T/T_D) and constant coherence number n_c on the appropriate part of the $PT_D/\delta T_D$ plane.

For model parameters in the locally unstable region, the exact solution of equation (6), which can be obtained by numerical integration, takes the form of a self-sustaining oscillation. For some parameter values this is a simple limit cycle, whereas for

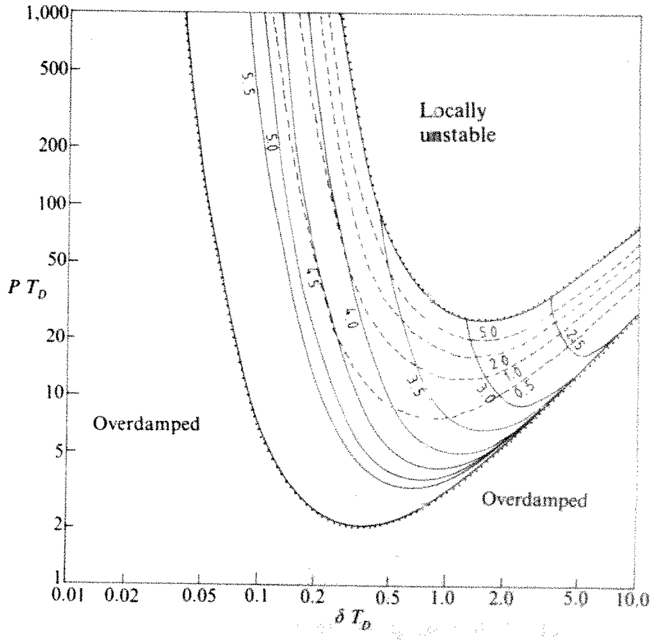

Fig. 4 Characterization of quasi-cyclic behaviour in the stable/underdamped region. Contours of constant normalized period T/T_D (———) and coherence number (– – – –) in the $PT_D/\delta T_D$ plane.

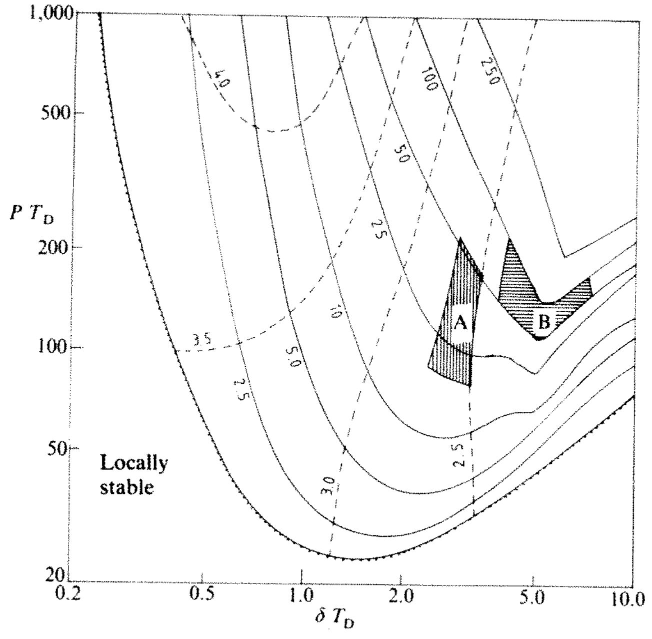

Fig. 5 Characterization of limit cycle behaviour in the locally unstable region. Contour of constant normalized period T/T_D (– – – –) and population ratio $N_{\max}/N_{\min}$ (———) in the $PT_D/\delta T_D$ plane. The area marked A shows the best fit parameters for the data of Fig. 1*a* and the area marked B corresponds to the data of Fig. 1*b*.

others it is a more complex cycle or is even formally aperiodic. In all cases, however, a spectral analysis of the solution reveals a single clearly marked dominant period (T). We have therefore characterized the solutions in this region by the ratio of this dominant period to the development delay (T/T_D) and the ratio of maximum to minimum population observed during the cycle ($N_{\max}/N_{\min}$). In Fig. 5 we plot contours of these quantities in the appropriate part of the $PT_D/\delta T_D$ plane.

An experimental test

As a quantitative test of our model, we now determine the parameter values which give the best fit to the gross characteristics (T/T_D and $N_{\max}/N_{\min}$ or n_c) of the fluctuations in the adult population of Nicholson's blowfly cultures, and then compare these best fit values with independent experimental estimates of the same quantities. We restrict our attention to the adult food-limited case (Fig. 1*a*), because only here do the data allow us to make an accurate independent estimate of the maximum *per capita* fecundity (P).

There is no simple test which will tell us *a priori* whether the fluctuations shown in Fig. 1*a* are self-sustaining limit cycles or driven quasi-cycles, so we must determine the best fit parameters under both hypotheses. If we assume that the fluctuations are of limit cycle type, then our quantitative characterization requires us to measure the maximum to minimum population ratio $N_{\max}/N_{\min}$ and the normalized cycle period T/T_D; quasi-cyclic fluctuations we characterize by $\bar{T}/T_D$ and the coherence number n_c. Examination of Fig. 1*a* combined with our previous identification of the correct value of the delay T_D as 14.8±0.4 days reveals that these quantities lie in the ranges

$$2.5<(T/T_D)<2.7; \quad 29<(N_{\max}/N_{\min})<53; \quad 2<n_c<5 \qquad (8)$$

which enables us to infer from the contour maps given in Figs 4 and 5 that the best fit values of the controlling parameters PT_D and δT_D for the limit-cycle hypothesis are

$$PT_D=150\pm70 \quad \delta T_D=2.9\pm0.5 \qquad (9a)$$

and for the quasi-cycle hypothesis

$$PT_D=23.5\pm4.5 \quad \delta T_D=3.0\pm0.7 \qquad (9b)$$

Although the best fit values of δT_D required under the two hypotheses are essentially indistinguishable, it is clear that the appropriate values of PT_D differ by more than a factor of 6. Thus, an independent estimate of the maximum *per capita* fecundity P will provide a clear *a posteriori* test of the mechanism underlying the observed cycles. We can easily obtain such an estimate from the egg-laying rate data in Fig. 1*a* by recognizing that, because the adult population minima are clearly below the maximum of the total reproduction curve, the value of P is simply given by

$$Pe^{-1}=\frac{\text{Maximum rate of egg-laying}}{\text{population producing maximum reproduction}} \qquad (10)$$

The value of P thus inferred from Fig. 1*a* is in the range 7.4 per day $<P<11.4$ per day, so that our final independent estimate of the controlling parameter PT_D is

$$PT_D=130\pm30 \qquad (11)$$

which is clearly compatible with the value required under the limit cycle hypothesis and absolutely incompatible with the quasi-cycle hypothesis. This, together with the fact that an independent estimate of δT_D is in good general agreement with the values required under both hypotheses, gives us considerable confidence that the fluctuations observed by Nicholson in the adult food-limited case are of limit-cycle type.

Separate generations in cycling populations

Our rather simplistic initial characterization of the non-linear behaviour of equation (6) in the limit-cycle region in fact conceals a wealth of complexity, for the formal repeat period of the cycles can often be many times the empirically observed dominant period. The general pattern is very similar to that seen by Mackay and Glass[9] and May[10] in equations of similar structure; close to the local stability boundary the solution is a simple limit-cycle with period T, but moving deeper into instability produces a number of successive doublings of the repeat time until a region is reached where the solution is formally aperiodic (chaos). Beyond the chaotic region we again see cyclic fluctuations.

These variations in the fine structure of the adult population fluctuations, although mathematically fascinating, are likely to be hard to identify experimentally in the presence of realistic levels of experimental uncertainty. However, the accompanying variations in the predicted pattern of reproductive activity are not only sufficiently dramatic to be easily identified experimentally, but also provide a clear explanation of Nicholson's observation that, in certain experimental circumstances, breeding occurred in quasi-discrete 'generations' but that in others it was much more nearly continuous. The mechanism by which separation of generations can occur in our model is illustrated in Fig. 6. When the minimum adult population in the trough of the cycle ($N_{\min}$) is greater than the population size at which maximum total reproduction occurs, N_0, then breeding activity ($R(N)$) is essentially continuous with one broad peak per cycle (Fig. 6*a*). When $N_{\min}$ is slightly less than N_0 (Fig. 6*b*), the pattern is still much the same but the reproduction rate peak now has a distinctive 'double-humped' shape. However, when $N_{\min} \ll N_0$, the pattern changes dramatically. In simple cases such as Fig. 6*c*, each adult population peak generates two narrow discrete generations, whereas in more complex cases such as Fig. 6*d*, when the adult population variation is only quasi-periodic, the generations are also very variable in size.

We have tested the plausibility of this mechanism as an explanation of Nicholson's observations by comparing the

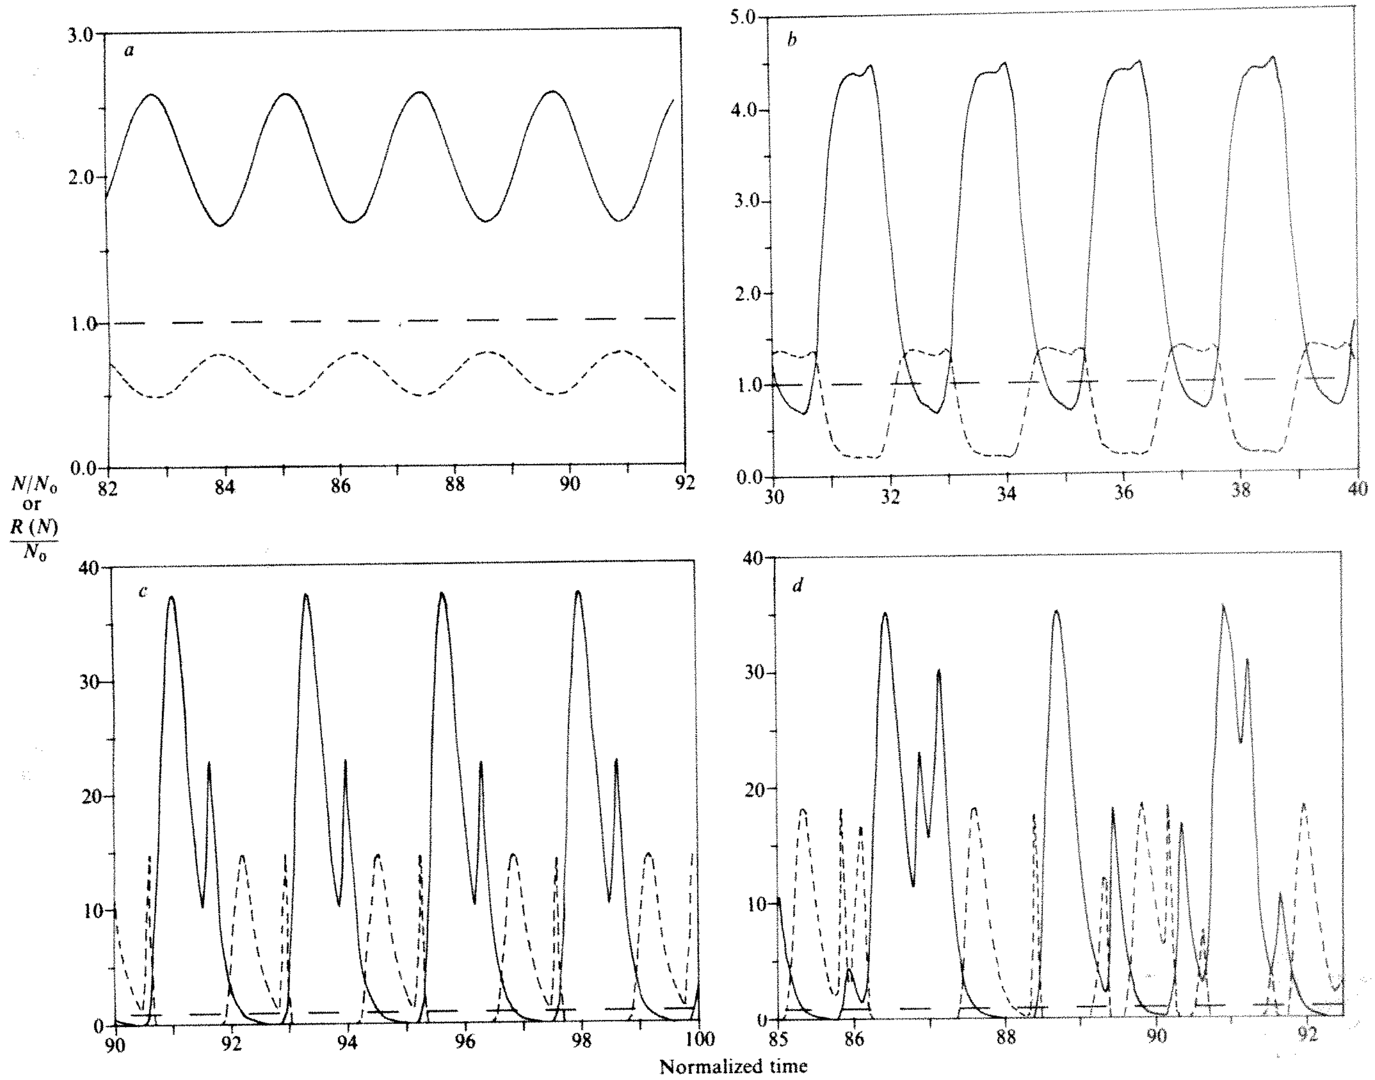

Fig. 6 Separation of generations in a cycling population. Normalized adult population (———) and normalized future recruitment rate (– – – –) as functions of time. *a*, $N_{\min} \gg N_0$: continuous reproduction; *b*, $N_{\min} \sim N_0$: one generation per cycle; *c*, $N_{\min} \ll N_0$: two generations per cycle; *d*, $N_{\min} \ll N_0$ and adult fluctuations aperiodic: complex generation pattern.

patterns of breeding activity predicted by our model with best fit parameters determined from the adult population fluctuations shown in Fig. 1*a* and *b*. For the adult food-limited case (Fig. 1*a*), we predict a single double-humped peak per population cycle, whereas in the larval food-limited case (Fig. 1*b*), we predict that breeding should take place in clearly distinguishable generations occurring at uneven time intervals. It is clear from the egg-laying rate and pupal population data given in Fig. 1*a* and *b*, respectively, that this strongly marked qualitative change is indeed observed experimentally.

Conclusions

The model described above provides a satisfying qualitative fit to Nicholson's blowfly data, and its extreme simplicity thus allows us to deduce that the observed fluctuations arise from the combination of a long development delay with a single-humped total reproduction curve. Moreover, it seems clear that any model containing these two generic features must behave in a generally similar way, so that our picture of the way in which discrete generations may be spontaneously maintained in cycling populations should in fact be rather generally applicable.

This model may thus be the prototype of a family of models which will unify the hitherto diverse 'discrete generation' and 'overlapping generation' views of insect population dynamics and lead to a clearer understanding of the uneven timing of insect generations both in the constant environment of the laboratory and in the variable environments encountered in the field. However, considerable further development will be required before we can fully assess the potential of the framework provided by such models to elucidate the subtle systematic differences in behaviour between various populations. As the range of technically feasible modifications is immense, we strongly believe that further development can only be done efficiently in conjunction with a comprehensive experimental programme.

One of us (S.B.) received an NIED postgraduate grant during this work.

Enkephalin blocks inhibitory pathways in the vertebrate CNS

R. A. Nicoll, B. E. Alger & C. E. Jahr

Departments of Pharmacology and Physiology, University of California, San Francisco, California 94143

Enkephalin markedly attenuates a variety of GABAergic inhibitory pathways in the CNS, but does not affect the action of GABA. The action of enkephalin is reversed by the specific opiate antagonist, naloxone. Thus, inhibitory interneurones may be primary targets for opioid peptide-containing pathways and disinhibition may be of general importance for opioid peptide action in the CNS.

OPIATE receptors and opioid peptides have been found in a variety of central nervous system (CNS) structures[1]. However, the distribution of these receptors and peptides gives little indication of their possible physiological role. The cellular action of opiates and opioid peptides in the CNS has been the subject of a number of reports (for review see ref. 2). There is considerable evidence of a presynaptic inhibitory role for opioid peptides[3–6] as well as a direct postsynaptic inhibitory action[2,7]. In the CNS, iontophoretic application typically inhibits the firing of sensitive neurones. However, a survey of opioid effects on neuronal activity in several brain regions of the rat revealed naloxone-reversible excitatory effects, and in the hippocampus 90% of the pyramidal cells encountered were strongly excited by enkephalin[7]. Further *in vivo* iontophoretic studies by Zieglgänsberger *et al.*[8] suggested that this excitation may be mediated indirectly by inhibition of neighbouring inhibitory interneurones, resulting in a disinhibition of pyramidal cells. Several recent studies, using primarily extracellular field potential and unit recording in slice preparations, support the proposal that enkephalin depresses the inhibition of pyramidal cells[9–15]. However, a number of questions remain. For instance, different studies have suggested preferential opiate effects on recurrent, or alternatively, on feedforward inhibition, and the site of the opiate effects, whether pre- or postsynaptic, is unknown[11]. Direct effects on excitation have not been ruled out, and there has been some question about the naloxone reversibility of the opiate action[16]. To some extent these difficulties can be attributed to the use of field potential and extracellular unit recording techniques, the results of which may be difficult to interpret. Here, we have used the hippocampal slice preparation and intracellular recording to analyse the cellular actions of enkephalin. In addition, we have extended these results to the *in vitro* olfactory bulb and spinal cord.

Enkephalin blocks i.p.s.ps in hippocampal pyramidal cells

The rat hippocampal slice preparation used in our experiments has been described elsewhere[17]. Stimulating electrodes were placed on the alveus for antidromic activation and in the stratum radiatum for orthodromic activation of pyramidal cells. Pentobarbital (0.1 mM) was added to the perfusate in some experiments, not only to enlarge and prolong the inhibitory postsynaptic potentials (i.p.s.ps), but also to unmask a feedforward, dendritic form of inhibition[17]. The stable enkephalin analogue, D-Ala^2-Met^5-enkephalinamide (DALA), was used in most experiments and was applied by bath perfusion in known concentrations.

We first tested the effects of DALA on field potentials recorded from the stratum pyramidale in response to orthodromic and antidromic stimulation. In the presence of DALA (5 μM), the size of the initial pyramidal population spike increases and additional population spikes appear, although there is no change in the amplitude of the antidromic response (Fig. 1). The facilitation of orthodromic responses is entirely reversed by the addition of naloxone. Concentrations of DALA as low as 10^{-8} M were effective, whereas morphine and Met-enkephalin required 10–100-fold higher concentrations. These findings (see refs 9, 10, 12–15) indicate that opiates, by activating opiate receptors, markedly enhance the excitatory synaptic responses of pyramidal cells, while having no demonstrable effect on antidromic responses.

To determine the mechanism for this profound and selective action, we have used intracellular recording from CA1 pyramidal cells. The left-hand column of Fig. 2 illustrates responses to antidromic stimulation and to two intensities of orthodromic stimulation, recorded with a potassium methylsulphate-filled electrode. The substantial reduction in the deflections caused by hyperpolarizing current pulses indicates that there is a fall in membrane resistance during the i.p.s.p. The i.p.s.p. produced by antidromic stimulation is of short duration and thought to be generated by a collateral feedback, interneuronal circuit mediated by γ-aminobutyric acid (GABA)[18]. The orthodromic i.p.s.p. evoked by high intensity stimuli has an additional depolarizing component which is considered to be generated by a feedforward pathway involving a set of GABA interneurones distinct from those involved in the feedback pathway[17]. DALA has little effect on the membrane potential or resistance of pyramidal cells, and the size of both the orthodromic and antidromic evoked i.p.s.p. is decreased. However, we have consistently found that feedforward inhibitory potentials to orthodromic stimulation are attenuated to a considerably greater extent than the responses to antidromic stimulation

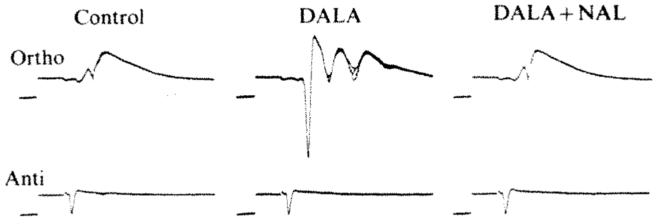

Fig. 1 Effect of opioid peptide (DALA) on field potentials in the hippocampal slice. The left-hand traces show the control responses recorded with an extracellular electrode in the pyramidal cell layer to antidromic (Anti) and orthodromic (Ortho) stimulation. The sharp downward deflections represent the synchronous firing of pyramidal cells and are termed population spikes. The middle traces show that exposure to 5 μM DALA greatly augments the orthodromic population spike and creates later population spikes while having no effect on the antidromic responses. Addition of naloxone (2 μM) to the DALA solution (DALA + NAL) completely reverses the effects of DALA. The calibration pulse at the beginning of each trace is 2 mV and 5 ms.

0028–0836/80/360022—04$01.00

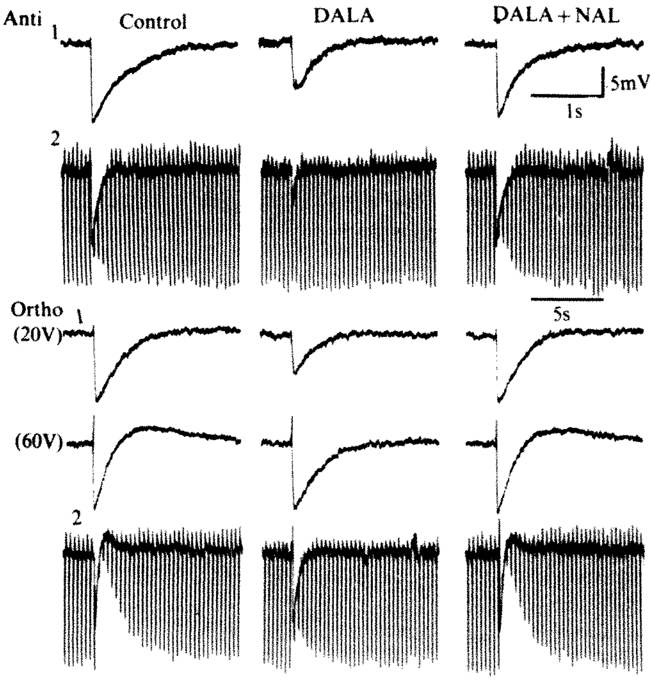

Fig. 2 Opioid peptide (DALA) antagonizes evoked i.p.s.ps in a hippocampal pyramidal cell. The responses to antidromic stimulation are shown at a fast (Anti$_1$) and a slow (Anti$_2$) chart speed with constant current hyperpolarizing pulses. The orthodromic responses are shown at a fast chart speed (Ortho$_1$), and at a low (20 V) and high (60 V) stimulus intensity. Note the late slow depolarization with high intensity stimulation. The response to high stimulus intensity is also shown at a slow chart speed (Ortho$_2$) with constant current hyperpolarizing pulses. The gain is the same in all records. The left-hand column shows the control responses. The records in the middle column were obtained 12 min after switching to 5 μM DALA, and the records in the right-hand column were obtained 15 min after adding 2 μM naloxone to the DALA-containing solution. The bathing medium contained 10^4 M pentobarbital. The resting membrane potential of this cell was −65 mV.

which are generated exclusively by a feedback pathway. In control conditions, orthodromic stimulation elicits a single action potential in pyramidal cells, whereas in the presence of DALA, multiple spikes are usually generated. In all 24 cells examined, DALA attenuated i.p.s.ps and thereby facilitated the ability of an excitatory postsynaptic potential (e.p.s.p.) to fire the cell. These effects of DALA were entirely reversed by naloxone, which by itself had no effect. The attenuation of the i.p.s.p. by DALA was also seen with KCl-filled electrodes, which reversed the i.p.s.ps into large depolarizing potentials (Fig. 3) and resulted in many spontaneous potentials appearing on the baseline (Fig. 4). These depolarizing spontaneous potentials, which are never seen in CA1 pyramidal cells when electrodes are filled with impermeant anions, are blocked by GABA antagonists, prolonged by pentobarbital and abolished by tetrodotoxin[19]. Because true quantal release (release of individual packets of transmitter) is resistant to tetrodotoxin blockade of electrical excitability[20], we conclude that these potentials represent small i.p.s.ps generated by the spontaneous discharge of inhibitory interneurones. With KCl-filled electrodes, cells typically hyperpolarized a few millivolts when exposed to DALA; this resulted from a cessation of spontaneous i.p.s.ps ($n = 7$). The film records in Fig. 4 illustrate this blocking action of DALA on the potentials and its reversal by naloxone.

The present findings indicate that the primary effect of DALA on pyramidal cells is indirect and involves a disinhibition, as proposed previously[8]. Although the effects of GABA antagonists are virtually identical to those reported here for DALA (see also refs 9–15), the DALA antagonism does not occur at the level of the GABA receptor, because the responses to exogenous GABA are not antagonized by DALA (Fig. 3). We consider the blockade of spontaneous i.p.s.ps by DALA to suggest that DALA exerts its effect at the level of the cell body of the inhibitory interneurone, suppressing cell discharge, although a more direct action on GABAergic synaptic terminals[3–6] cannot be excluded by these results. It is interesting that the opiate receptor distribution in the CA1 region determined autoradiographically[21] would agree well with the location of interneurones thought to mediate inhibition[18]. Immunohistochemical studies of the hippocampus[22] suggest that the enkephalin-containing fibres and terminals are present mainly in the very small CA2 field. Perhaps a non-enkephalin, opioid-containing fibre system exists in CA1, or perhaps enkephalin is capable of diffusing from CA2 to the nearby CA1.

Enkephalin blocks dendrodendritic inhibition in the olfactory bulb

We have examined the effects of DALA on other forms of inhibition in the CNS to determine how widespread a phenomenon disinhibition might be. We have recently developed an isolated turtle olfactory bulb preparation to examine dendrodendritic inhibition of mitral cells, using intracellular recording[23]. In all cells tested ($n = 7$), DALA markedly attenuated i.p.s.ps evoked either orthodromically or antidromically, and was particularly effective against those generated at reciprocal synapses by direct depolarization of the mitral cell (Fig. 5, middle column). This effect occurred with little change in the resting membrane properties of mitral cells. Moreover, naloxone could reverse the i.p.s.p. depression (Fig. 5, right-hand column). Because the directly evoked i.p.s.p. is generated solely by dendritic reciprocal synapses, DALA seems to be acting directly on the reciprocal synapses. This site of action agrees with neurochemical and anatomical results. Opiate receptor binding is high in the layers of the bulb in which reciprocal synapses exist[24]. Anatomical studies[25,26] have shown that centrifugal fibres do not make direct contact with mitral cells, but end exclusively on inhibitory interneurones. Of particular interest is the finding that some of the centrifugal fibres synapse directly onto the gemmules of granule cells, the structures which form the reciprocal synapses[25,26]. It will be of interest to see if some of these centrifugal fibres contain enkephalin.

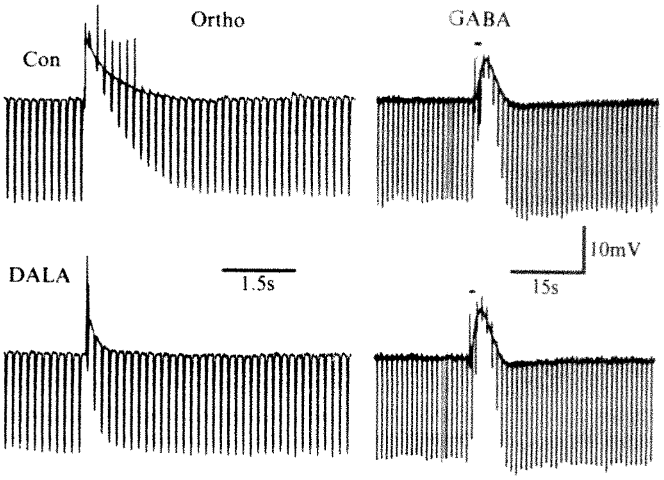

Fig. 3 Opioid peptide (DALA) is not a GABA antagonist. The upper traces show the response to orthodromic stimulation (Ortho) and to an iontophoretic GABA pulse (80 nA) applied to the apical dendrites and recorded from the soma of a pyramidal cell. The lower records were obtained 5 min after switching to a 5 μM DALA-containing solution. The cell hyperpolarized 3 mV, resulting in a slight increase in the GABA responses. The orthodromic response is markedly curtailed. The bathing medium contained 10^{-4} M pentobarbital. The membrane potential was −52 mV. The recording electrode was filled with 3 M KCl.

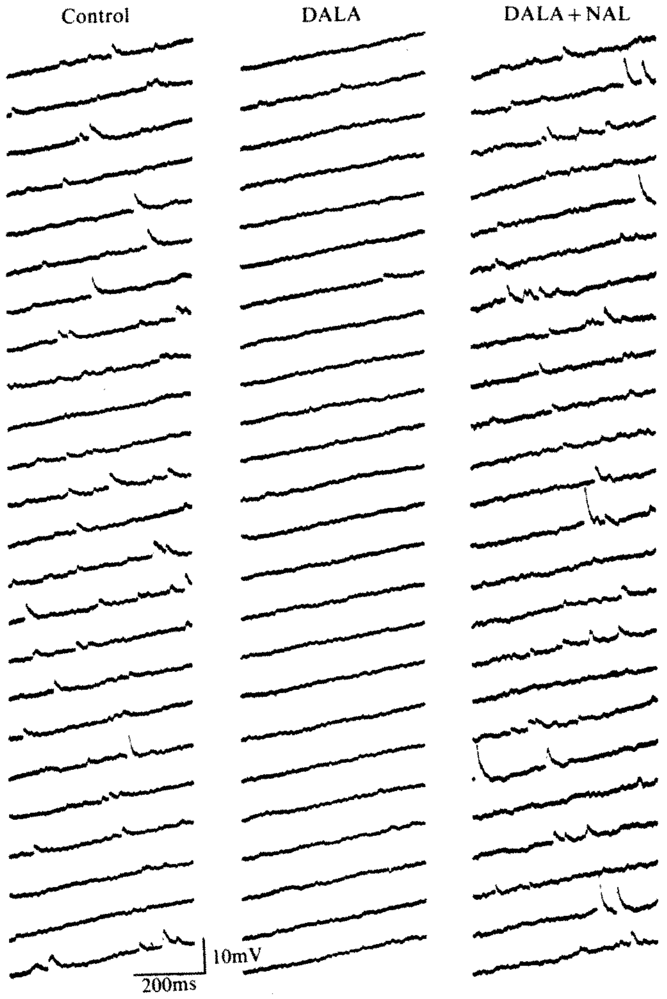

Fig. 4 Opioid peptide (DALA) blocks spontaneous i.p.s.ps in hippocampal pyramidal cell. The responses were recorded on running film with a 3 M-KCl filled microelectrode in the absence of pentobarbital. To block spontaneous action potentials the membrane was hyperpolarized to −69 mV while the film records were obtained. Switching to a solution containing 5 μM DALA for 6 min eliminates the spontaneous depolarizing potentials. Addition of 2 μM naloxone to the DALA-containing solution reverses the depressant action of DALA. The resting membrane potential was −53 mV in control, −56 mV in DALA and −50 mV in DALA+NAL. The faster decay of the potentials in DALA+NAL was due to a fall in membrane resistance resulting from imperfect sealing of the electrode when these records were obtained.

Enkephalin blocks presynaptic inhibition in the spinal cord

Finally, we have tested the effects of DALA on presynaptic inhibition in the isolated spinal cord of the frog in 20 preparations. The techniques used to stimulate and record from this preparation have been described previously[27]. In this preparation, stimulation of the ventral root depolarizes primary afferent terminals. This response can be recorded from the dorsal root with extracellular electrodes and is referred to as a dorsal root potential (d.r.p.)[28,29]. We have found that DALA produces a remarkable and almost complete block of both the d.r.p. (Fig. 6*A*, *B*) and the accompanying inhibition of primary afferent transmission (Fig. 6*C*). This effect is quite selective, for at a time when the d.r.p. is virtually abolished, synaptic excitation by large myelinated primary afferents is either unaffected or actually enhanced. The d.r.p. evoked by stimulating an adjacent dorsal root is less sensitive to DALA. However, both the rising phase of the d.r.p. and the dorsal root reflex (which are considered to be mediated by GABA[30,31]), are depressed by DALA. Although Met-enkephalin and morphine produced effects similar to DALA in the spinal cord, approximately 100-fold higher concentrations were required. A similar depression of d.r.ps by enkephalin and morphine has been observed in the isolated rat spinal cord[32] and intact cat[35,36].

In addition to depressing d.r.ps, DALA hyperpolarizes primary afferents. This effect is due partly to a block of the spontaneously occurring d.r.ps (Fig. 6*A*) and partly to a direct action on the terminals, as the hyperpolarization is not abolished when synaptic transmission is blocked by magnesium or tetrodotoxin. The block of d.r.ps, presynaptic inhibition and the hyperpolarization are all completely reversed by naloxone (Fig. 6*A*). GABA, or a closely related neutral amino acid, is thought to be the transmitter responsible for depolarization of primary afferents[27,29,31]. However, as in the case with hippocampal pyramidal cells, the actions of GABA (Fig. 6*B*) and β-alanine on primary afferents is unaffected by DALA at a time when the d.r.ps are abolished. Therefore, the action of DALA must occur at some earlier step in this pathway, possibly on cell bodies of presynaptic inhibitory interneurones or directly on the axo-axonic synapses.

Concluding remarks

We have found that excitatory opiate effects in various parts of the vertebrate CNS are caused indirectly, and actually occur as the result of disinhibition. These forms of inhibition include feedforward and recurrent inhibition of hippocampal CA1 pyramidal cells, dendrodendritic postsynaptic inhibition of olfactory bulb mitral cells, and presynaptic inhibition of spinal primary afferents. Because enkephalin does not antagonize the action of GABA, the putative neurotransmitter for these inhibitory pathways, a depression of inhibitory interneurone excitability and/or a block in GABA release from nerve terminals are likely explanations for the disinhibition caused by enkephalin. The depression of putative inhibitory neuronal firing by enkephalin, reported by others, would favour the former explanation[8,13].

Such a disinhibitory mechanism at supraspinal sites could help explain the epileptic activity seen following administration of opioid peptides[33,34]. Although morphine is relatively ineffective in blocking i.p.s.ps, generalized seizures have been reported following high systemic doses[37]. Furthermore, the present findings suggest that disinhibition may be an important general mechanism of opioid action in the CNS and that local, GABA-containing, inhibitory interneurones are primary targets of enkephalin-containing fibre systems. Such neurones are thought to have a key role in integrating neuronal information within a given region. Very small changes in the release of enkephalin would, by modifying the spontaneous activity of inhibitory

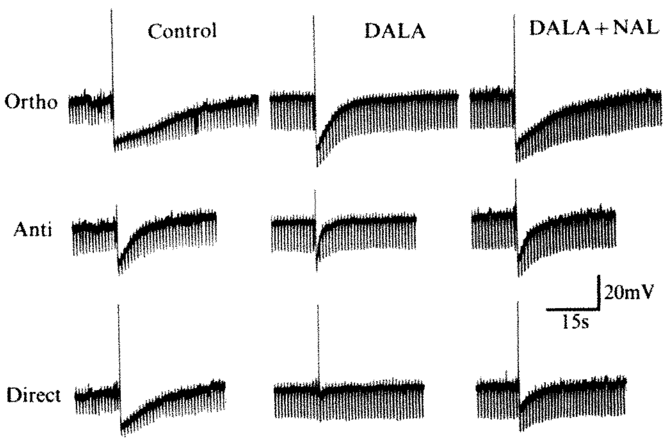

Fig. 5 Opioid peptide (DALA) blocks i.p.s.ps recorded intracellularly from an olfactory bulb mitral cell. The top records were obtained by stimulating the olfactory nerves, the middle records by mitral cell axon stimulation, and the bottom records by direct depolarizing current pulses which discharged the cell. The left-hand column shows the control responses. The middle column shows the responses obtained 20 min after perfusion with a Ringer containing 10 μM DALA. The right-hand column was obtained 40 min after the addition of 7 μM naloxone to the enkephalin-containing Ringer solution. The downward deflections represent responses to constant current hyperpolarizing pulses. The microelectrode was filled with 3 M potassium methylsulphate. The membrane potential of this neurone was −55 mV.

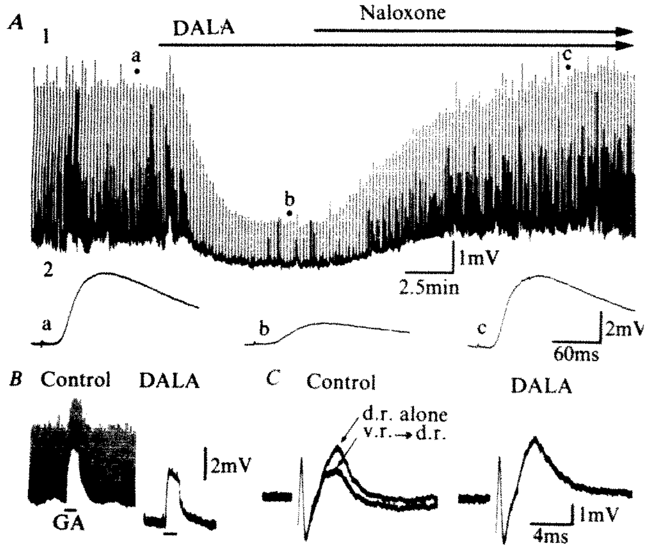

Fig. 6 Opioid peptide (DALA) blocks dorsal root potentials in the isolated frog spinal cord. A_1 shows a continuous recording with sucrose gap from the dorsal root. Dorsal root potentials (d.r.ps) (upward deflections) were evoked by stimulating a ventral root. 5 μM DALA greatly reduced the spontaneous and evoked d.r.ps. Naloxone (2 μM) reverses the effects of DALA. A_2 shows sample film records of the d.r.p. evoked at the times indicated by the small letters. *B* shows that DALA (10 μM) has no effect on the GABA sensitivity of the primary afferents at a time when it abolishes d.r.ps (upward deflections). The time scale is the same as in A_1. *C* shows superimposed film traces recorded with an extracellular electrode positioned in the dorsal horn. Stimulation of the dorsal root elicits a fast presynaptic fibre spike followed by a slow postsynaptic response (d.r. alone). Stimulation of the dorsal root 40 ms after a conditioning ventral root stimulus, at the peak of the d.r.p., results in a decreased postsynaptic response (v.r.→d.r.). DALA (10 μM) which completely abolished the d.r.p. in this preparation also blocks the decrease in the postsynaptic response.

interneurones, result in profound changes in the propagated output of principal cells.

In general, we can conclude that the cellular localization of neurotransmitter receptors may be more meaningful than their overall density in determining the relative importance of the neurotransmitter in a particular CNS region. In the present case, opioid peptides have physiological effects which would at first glance seem to be disproportionately large in comparison with the modest concentration of endogenous peptides or opiate receptors. These effects can be accounted for by the findings that opiate receptors occur at strategic sites for the control of neuronal activity in the structures investigated. This emphasizes the importance of considering transmitter effects in the context of the intrinsic neuronal circuitry of a given CNS region rather than assessing the drug responsiveness of single neurones.

A soft X-ray halo around SU UMa

The dwarf nova SU UMa was observed with the imaging proportional counter (IPC) detector[1] on the Einstein X-Ray Observatory on 4 October 1979 at 4 h UT for ~3,000 s. An X-ray source was detected at the position of the star. It had a flux of 1.3×10^{-11} erg cm^{-2} s^{-1} (0.6 counts per s) in the 0.1–4.5 keV energy range of the IPC, assuming a spectral temperature of ~10 keV (ref. 2). In addition, several areas of weaker emission were observed which form a ring that is symmetrically disposed about the position of the dwarf nova. This latter emission is detected only at energies below 0.7 keV. We discuss here the possibility that it arises in material that has been ejected from the star in a nova-like event.

An X-ray map of the SU UMa field is displayed in Fig. 1: the contours of equal X-ray intensity that are plotted show the relatively bright central source surrounded by a patchy distribution of enhanced X-ray emission. The mean radius of this 'ring' is ~14 arc min. The apparent knots of emission in the ring, of scale size ~1 arc min, are typically ~7 ± 3 counts above background. Additional structure may be present within the confines of the ring, particularly to the north-west of the dwarf nova. An examination of a large number of IPC fields demonstrates that this ring-like structure is unique to SU UMa and is not an instrumental effect.

To investigate the structure and luminosity of this feature further, we have summed the counts as a function of radius from the position of the central source in two energy bands. This is plotted in Fig. 2 which shows the counts accumulated in channels 1–4 and 5–14 of the 15 channel pulse-height analyser. Using the detector gain calculated from calibrations performed on the day of the observation, these channels encompass energy bands of 0.09–0.72 and 0.72–4.31 keV. The expected decrease of the counts as a function of radius from the centre of the field of view, caused by vignetting of the telescope, is shown by the dashed lines. The data in the higher energy band are distributed in a manner consistent with this function. However, at low energies

0028–0836/80/360025—03$01.00

there is an excess above the vignetting curve at a radius of $\sim$14 arc min, attributable to the ring. This feature thus seems to be most prominent at low energies.

The total number of counts in the knots comprising the ring (including the north-west filament) is $\sim$13% that of the central source. This actually represents a lower limit to the ring intensity as much of the halo emission could come from extended regions whose surface brightness is too low to appear significant in the present data. Based on the lack of detection of the ring above $\sim$0.7 keV, we estimate its temperature to be of the order of 10^6 K. Using this temperature we calculate the integrated flux from the ring to be $\sim 6\times10^{-13}$ erg cm^{-2} s^{-1}, with an estimated uncertainty of 30%.

The symmetrical distribution of the ring around SU UMa suggests that it might be emission from material ejected by that object. It is unlikely that this material is radiatively excited by emission from the central star, as is the case in planetary nebulae, for example. The calculations of Tarter *et al.*[3] allow us to estimate the temperature of a spherically symmetric, optically thin gas cloud irradiated by a central point source of X rays as a function of the parameter $\xi = L/nr^2$, where L is the luminosity of the central source, n is the gas density and r is the distance of the gas from the central star. At an assumed distance of 100 pc, $L \sim 1.5\times10^{31}$ erg s^{-1} and $r \sim 0.4$ pc. Thus for SU UMa, $\xi \sim 1\times10^{-4}[(0.1\ \text{cm}^{-3})/n]$. This implies a temperature $<10^4$ K, clearly inconsistent with the soft X-ray temperature observed in this observation.

Alternatively, we consider a mechanism analogous to that which gives rise to X-ray emission from Supernova remnants, that is, a blast wave from a nova explosion propagating through the interstellar medium (ISM) and shock heating the ambient material. If the density of the ISM is 0.06 cm^{-3}, which is appropriate for the galactic latitude of SU UMa[4] ($b = 33°$), the total amount of material swept up by a shock of radius 0.4 pc is $\sim 4\times10^{-4}\ M_\odot$. This is larger than the mass typically ejected in a nova explosion[5] ($\sim 10^{-4}\ M_\odot$), so that it is reasonable to assume that the blast wave is in the adiabatic phase (see ref. 6). Adopting $T \sim 10^6$ K and a 0.2–2.0 keV luminosity of $\sim 10^{30}$ erg s^{-1} for the ring, the standard adiabatic solution gives a shock velocity, $V_s \sim 300$ km s^{-1}, an initial explosion energy, $E_0 \sim 10^{45}$ erg, a density for the ISM, $n \sim 0.1$ cm^{-3}, and an expansion age, $t \sim 500$ yr. The explosion energy required by the adiabatic model is similar to the energy liberated in a nova outburst[7], while the ISM density derived is compatible with the expected value of 0.06 cm^{-3} (ref. 4). This interpretation of the X-ray ring is thus self-consistent.

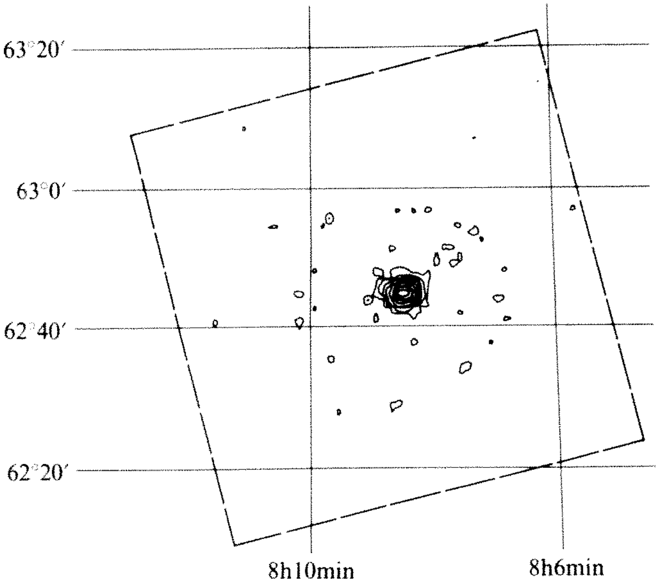

Fig. 1 The isointensity X-ray contour map of the $\sim1°\times1°$ IPC field (delineated by the dotted line boundary) centering on SU UMa. The size of the central object is consistent with the IPC spatial response to a point source (FWHM $\sim$2.3 arc min). Centred approximately symmetrically around the central star at a radius of $\sim$14 arc min is a nonuniform ring of emission.

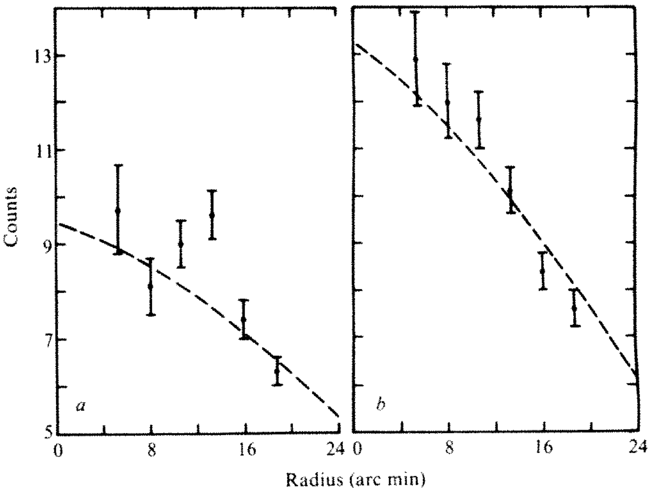

Fig. 2 The radial distribution of the intensity of the SU UMA field. The counts were integrated over radial rings in increments of 2.67 arc min extending outwards from the central source; the counts shown here have been normalized to a 2.67×2.67 arc min area: *a*, for the soft X-ray band of 0.1–0.7 keV and *b*, for the hard X-ray band of 0.7–4.3 keV. (The central source is not depicted as its count rate goes off scale.) The dashed lines represent the normalized effective area function of the IPC field (which depends on energy as well as spatial distribution); it also includes the vignetting function of the Einstein focusing telescope. Only in the soft X-ray band (*a*) is an enhancement above this function evident at the location of the ring.

A visual inspection of the region around SU UMa using the Palomar Sky Survey prints reveals no evidence for optical filamentary structure. The optical filaments associated with Supernova remnants are believed to be low temperature emission from relatively dense interstellar clouds[8,9]. The lack of such emission is to be expected in the present case if the halo resides entirely in the intercloud medium, as is likely given its small size compared with the mean diameter and separation of interstellar clouds[4].

The observation of an X-ray ring (that can be interpreted as resulting from a nova-like explosion) around an object that now shows the characteristics of a dwarf nova provides evidence for a connection between novae and dwarf novae. Other evidence that these two subclasses of cataclysmic variables may be related can be found in the fact that nova 1901 (GK Per) now exhibits dwarf nova-like behaviour[10], and Nova Vul 1979 reportedly exhibited similar behaviour for at least 80 yr before its outburst[11]. These findings may have important implications for evolutionary models of cataclysmic variables. As a possible first detection of an X-ray nova remnant, the X-ray ring around SU UMa provides a new parameter regime for exploring, as is done with Supernova remnants, the physical conditions in the interstellar medium and the physics of the nova outburst. A search for X-ray ejecta from other likely sources, including all types of cataclysmic variable stars, should also be made.

We were guest observers on the Einstein X-ray Observatory. We thank Dr F. R. Harnden of Harvard/SAO for invaluable computational assistance and comments regarding the final manuscript. Useful discussions with Drs S. Hatchett, B. Smith, and H. Bond are also acknowledged. This work was supported in part by the Department of Energy and NASA grant 5-25049. K.O.M. acknowledges financial support from the Miller Institute for Basic Research and NASA grant/NAGW-44.

Simultaneous IR and X-ray burst observation of Ser X-1

Walter H. G. Lewin & Lynn R. Cominsky

Department of Physics and Center for Space Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Alistair R. Walker & Bruce S. C. Robertson

South African Astronomical Observatory, PO Box 9 Observatory, 7935 South Africa

It has been suggested[1,2] that the very bright IR bursts[1,3] observed from the Rapid Burster (MXB 1730 − 335) are due to Type I X-ray bursts[4]. When the bright IR bursts were detected, unfortunately there was no simultaneous X-ray coverage. Therefore, it is not known whether the IR bursts are associated with Type I or Type II bursts or with neither one. The suggestion[1,2] is only based on the low recurrence rate of the IR bursts. If the suggestion is correct, similar bright IR bursts may, in general, accompany Type I X-ray bursts[1,2]. This paper investigates this possibility for one specific case. During the 1977 coordinated worldwide burst watch[5], simultaneous X-ray and IR observations were made. On UT June 17, 00 h 00 min 25s, a Type I X-ray burst was observed, which was almost certainly emitted by Ser X-1 (MXB 1837+05, 4U1837+04) (ref. 6). Simultaneous IR observations failed to detect any bursts. We report here on these observations.

Between UT June 16, 20 h 40 min and June 17 02 h 30 min, IR observations were made with the SAAO 30-inch telescope in Sutherland. The field of view was approximately centered on the star which was first identified by Davidsen[7]. It is now known that the actual star is ~ 2.2 arc s away[8], but that is of no consequence here since the radius of the field of view was ~ 35 arc s. A Glass MK2 IR photometer was used in combination with a lead sulphide detector. The observations were made at 2.2 μm using a Johnson K filter (bandwidth ~ 0.48 μm). The output was displayed on a chart recorder running at sufficient speed that the lock-in time constant of 1 s was the dominant smoothing factor. No indication of an IR burst was found. A 3σ signal in a 1-s readout corresponds to a peak K magnitude of ~ 7. Therefore, at a 3σ level of confidence, the IR flux integrated over the 20 s duration of the burst was less than 1.3×10^{-9} erg cm^{-2}.

SAS-3 observed Ser X-1 (MXB 1837+05, 4U1837+04) between UT 1977 June 11.6 and June 17.5. Between June 11.6 and 14.9 the source was observed with the Horizontal Tube (HT) system[9,10]. A total of nine Type I bursts were observed. From June 14.9 to June 17.5 the source was observed with the Center Slat (CS) system[9,10] (field of view $\sim 1.0° \times 30°$ FWHM) and a total of six bursts were observed. When a Type I X-ray burst occurred on June 17 00h 00 min 25 s, Ser X-1 was within a few arc min of the centre line of the CS and 9.8° from the spacecraft equator (elevation). Consequently, at the time of the burst, the collimator transmission function was 0.57 ± 0.03. The rise time of the burst was less than 1 s, the burst decayed gradually and lasted for about 20 s. The integrated burst flux, in the range 1.4–14 keV, was $(9.3 \pm 0.9) \times 10^{-8}$ erg cm^{-2}.

There is a chance that the X-ray burst did not come from Ser X-1; although it is not possible to calculate a formal probability, we believe this chance to be small. The burst was only observed in the CS and not in the HT system[9,10] ($\sim 1.7°$ FWHM). Thus, it could only come from sources viewed by the CS excluding the area of overlap with the HT system. This excludes the burst source Aql X-1 (ref. 11) since it was located near the centre of the HT system. The only known burst source other than Ser X-1 in the field of view of the CS system was Aql MXB (ref. 9). However, only 15% of the error box of Aql MXB was observed by the CS (and not by the HT system) and the burst frequency of Aql MXB is very low; only one burst was observed in 1976 in 12 days of observing[9]. In addition, a reanalysis at MIT of the 1976 SAS-3 data showed that the burst form Aql MXB (ref. 9) could have come from Aql X-1 (L. Cominsky, A. Lawrence and W. Lewin; unpublished data). If the burst sources Aql X-1 and Aql MXB are the same source, as we suspect, then Ser X-1 was the only known burst source in the field of view of the CS and not in the HT system.

There is another reason why we believe that the burst observed in the CS system was emitted by Ser X-1. Ser X-1 was burst active during the observations with the HT system from June 11.6 to 14.9 and the burst observed on June 17 00 h 00 min 25 s with the CS system was very similar to many from Ser X-1 observed a few days earlier with the HT system.

The ratio of the observed IR (2.2 μm, 0.48 μm bandwidth) and X-ray (1.4–14 keV) fluxes for the burst from Ser X-1 is less than 1.4×10^{-2} at a 3σ level of confidence. For stars in the direction of Ser X-1 ($l^{\mathrm{II}} \sim 36°$, $b^{\mathrm{II}} \sim 5°$), the colour excess $E_{\mathrm{B-V}} \sim 0.6$ mag kpc^{-1} (ref. 12). With a scale height of ~ 150 pc (ref. 13), the path through the dust layer along the line of sight to Ser X-1 is ~ 1.8 kpc. Thus, $E_{\mathrm{B-V}} \sim 1.1$ which yields corresponding values for the extinction[13] $A_{\mathrm{V}} \sim 3.3$ mag and $A_{\mathrm{K}} \sim 0.3$ mag. Thus, after correction for extinction, we find for the ratio of IR and X-ray fluxes an upper limit of 1.8×10^{-2} (3σ level of confidence). We will compare this with the flux ratios of IR bursts and Type I X-ray bursts (not observed simultaneously) from the Rapid Burster.

From the work by Kulkarni *et al.*[1] (1.6 μm, bandwidth 0.3 μm) and that of Jones *et al.*[3] (2.2 μm, bandwidth 0.4 μm), we calculated the integrated IR fluxes. The six IR bursts observed by the Indian group had an average duration of ~ 35 s and an average burst flux integrated over the duration of the bursts of $\sim 2.2 \times 10^{-8}$ erg cm^{-2}. Jones *et al.* observed two events and measured burst durations of ~ 20 s and ~ 12 s. The integrated IR flux values were $\sim 8.2 \times 10^{-9}$ erg cm^{-2} and $\sim 5.5 \times 10^{-9}$ erg cm^{-2}.

Using SAS-3 data (not taken simultaneously with the IR observation), we calculated the integrated fluxes of three Type I X-ray bursts of ~ 20 s duration form the Rapid Burster. All three bursts were observed with the HT system (1.7° FWHM) and in all cases, the Rapid Burster was within 0.3° of the centre of the field of view. The average value (corrected for aspect) in the 1.3–18 keV interval is $(1.0 \pm 0.1) \times 10^{-7}$ erg cm^{-2}.

Thus we find that the observed IR/X-ray (Type I) flux ratios are ~ 0.22 using the IR data by Kulkarni *et al.*[1], (H band) and ~ 0.07 (average value for the two events) using the IR data by Jones *et al.*[3] (K band). For the X-ray flux we used the SAS-3 data which were not taken simultaneously. After correction for extinction[13,14] ($A_{\mathrm{H}} \sim 2.0$; $A_{\mathrm{K}} \sim 1.1$), these flux ratios become ~ 1.38 and ~ 0.19 respectively. Thus they are respectively ~ 77 times and ~ 10 times larger than the 3σ upper limit reported in this paper for the Ser X-1 burst.

Optical bursts have been observed simultaneously with Type I X-ray bursts[15–18] from three burst sources, including Ser X-1 (ref. 17). The optical emission is believed to be due to X-ray heating of the accretion disk[16,17,19–21]. The disk is expected to radiate more or less as a black body of different temperatures whose emission reaches a maximum at energies considerably above those of visible photons. An extrapolation of its spectrum to the IR would predict flux levels several orders of magnitude below what would be detectable. Therefore, the fact that IR bursts were detected from the Rapid Burster excludes that they are related to optical bursts as observed in three other burst sources. If they are of thermal origin, the IR brightness temperatures would be in excess of 4×10^{10} K (ref. 3). It has been suggested that the IR fluxes are produced by maser action[2].

0028-0836/80/360027—02$01.00

The purpose of this paper is to see whether unusually strong IR fluxes as detected from the Rapid Burster (whose origin is still uncertain) accompany Type I X-ray bursts from Ser X-1. Our upper limit reported here indicates that the Type I burst from Ser X-1 was not accompanied by a bright IR burst. One could perhaps argue that the IR bursts are highly directional and that in the case reported here, for Ser X-1, the IR burst missed the Earth. However, if the IR beams are highly directional, they could not be associated with Type I X-ray bursts from the Rapid Burster. Since the Type I X-ray bursts from the Rapid Burster, when present, occur on time scales of hours, one would expect to detect IR bursts (if narrowly beamed) at a much lower rate. However, eight (of which six came in pairs) were detected in 7.9 h (refs 1, 3).

We conclude that if the Type I X-ray burst observed on UT June 17, 00 h 00 min 25 s came from Ser X-1, as is very likely, the possibly associated 2.2 μm IR integrated burst flux (K band) was less than 1.3×10^{-9} erg cm^{-2} (3σ level of confidence). This is substantially fainter than IR bursts observed from the Rapid Burster. However, the integrated fluxes observed in Type I X-ray bursts from the Rapid Burster and Ser X-1 are comparable. Thus, if Type I X-ray bursts are associated with the IR bursts, as suggested[1,2] the flux ratio IR/X-ray is substantially (one to two orders of magnitude) lower for the June 17, 1977 burst from Ser X-1 than for the Rapid Burster.

We suspect that Type I X-ray bursts are not associated with bright IR bursts and that the Rapid Burster is unique in producing the IR bursts, as it is unique in many other ways. If the IR bursts are associated with the Type II bursts from the Rapid Burster, the IR bursts must be highly anisotropic since their frequency of occurrence is considerably less than that of the Type II bursts[20,21].

We thank Dr Jan van Paradijs for his useful comments on this manuscript. L. C. was supported by the Zonta International Amelia Earhart Fellowship program. This research was supported in part by a grant from NASA (NAS5-24441).

Intracrystalline grafting on layer silicic acids

E. Ruiz-Hitzky & J. M. Rojo

Grupo de Físico-Química Mineral, Consejo Superior de Investigaciones Científicas, Serrano 115 dpdo., Madrid-6, Spain

Silanol groups (Si–OH) present at the surface of amorphous silica and microcrystalline silicates can react with organosilicon compounds to form stable organic derivatives[1–3]. The grafting reaction always occurs at the external surfaces of these materials. The present work considers the intracrystalline grafting on internal Si–OH groups in certain layer silicic acids. For the reaction to occur, the silicic acid must have been expanded by the intercalation of appropriate organic polar molecules such as dimethylsulphoxide; in this way, the individual layers of the silicic acid can be separated and the internal Si–OH groups become accessible to the grafting reagents. The resulting grafted products are organosilicic compounds which retain the lamellar structure of the starting silicic acids, but with the interlamellar surfaces covered by organic groups homogeneously distributed. These materials can be thought of as planar silicones.

Starting materials for the reaction are crystalline silicic acids obtained from natural or synthetic alkali layer silicates by acid treatment[4,5]. These silicic acids have a lamellar structure with intracrystalline Si–OH groups covering the interlamellar surfaces. α-$H_2Si_2O_5$, $H_2Si_8O_{17}.nH_2O$ and $H_2Si_{14}O_{29}.nH_2O$ are used in this work. The last silicic acid is called H-magadiite because it was prepared by acid treatment of the mineral magadiite[4]. Reagents used in the present investigation were trimethylchlorosilane (I) and hexamethyldisilazane (II) which react with the Si–OH groups of the mineral substrate to form siloxane bridges (Si—O—Si):

$$\equiv Si{-}OH + Cl{-}Si(CH_3)_3 \rightarrow \equiv Si{-}O{-}Si(CH_3)_3 + HCl \quad \text{(I)}$$

$$2\equiv Si{-}OH + (CH_3)_3SiNHSi(CH_3)_3 \rightarrow 2\equiv Si{-}O{-}Si(CH_3)_3 + NH_3 \quad \text{(II)}$$

Mixtures of both reagents can be also used with positive results.

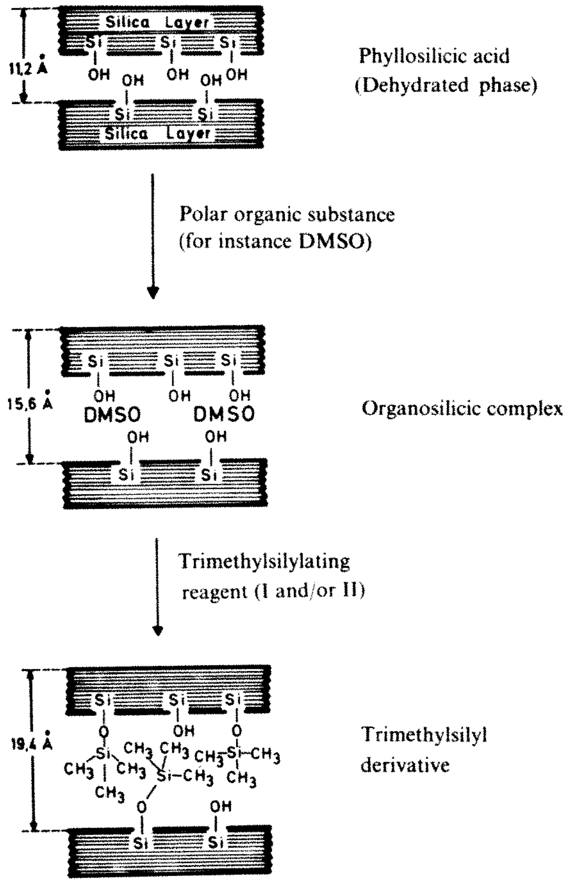

Fig. 1 Interlamellar grafting of $-Si(CH_3)_3$ groups. The synthesis of the trimethylsilyl derivative of the phyllosilicic acids was carried out in two steps: first, the starting silicic substrate (dehydrated phase) was added to an excess of an organic polar substance, as DMSO, and the mixture was stirred continuously for 72 h; excess DMSO was eliminated and the organosilicic complex was recovered. In the second step, reaction between this complex and the trimethylsilylating reagents (I and/or II) was carried out in dioxane for time periods ranging from 24 to 48 h at reflux temperature.

0028-0836/80/360028—03$01.00

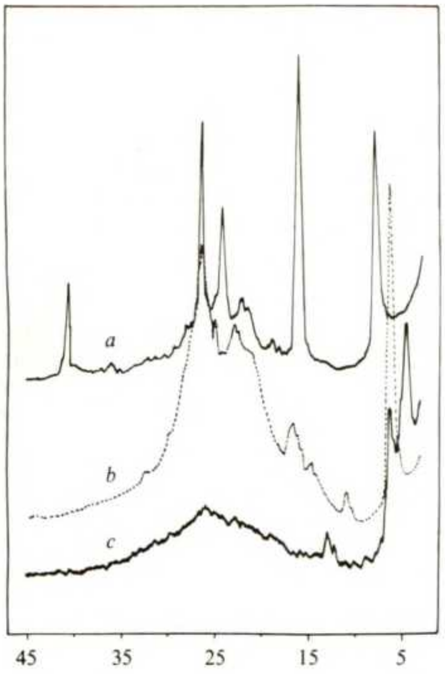

Fig. 2 X-ray diffraction patterns of: *a*, H-magadiite silicic acid, pretreated at 100 °C, 24 h; *b*, H-magadiite (*a*) treated by NMF (intermediate *a*/NMF complex); *c*, trimethylsilyl derivative of *a*, obtained by refluxing the *a*/NMF complex with a mixture of I and II reagents.

If the grafting reaction is carried out by direct treatment of the mineral substrate with organosilanes (I) and/or (II), the resulting product is an organosilicic material with $(CH_3)_3Si$– groups bonded only at the external surfaces of the mineral particles. However, if the silicic acid is previously treated with a polar organic substance such as dimethylsulphoxide (DMSO), *N*-methylformamide (NMF), or *N,N*-dimethylformamide, and subsequently reacted with (I) and/or (II) reagents, then an interlayer grafting on the internal Si–OH groups is produced. The intercalation of the above polar organic substances into the interlayer space of the phyllosilicic acids is a reversible process, as described by Lagaly *et al.*[5]. The swelling produced by these organic molecules makes the internal Si–OH groups accessible to the trimethylsilylating reagents, so that subsequent grafting reaction can occur. Figure 1 explains the different steps in the synthesis of the organosilicic materials.

Evidence of the interlayer grafting of the $-Si(CH_3)_3$ groups was obtained from X-ray diffraction diagrams. The basal spacing (d_{001}) of the phyllosilicic acids increased in all cases, with a mean value of $\Delta d = 8.2$ Å, corresponding to the thickness of two $-Si(CH_3)_3$ groups (Table 1). A disorder in the stacking of the lamellae of the silicic acids is produced during the grafting reaction, as indicated by the broadness of the peaks in the X-ray diffraction pattern (Fig. 2).

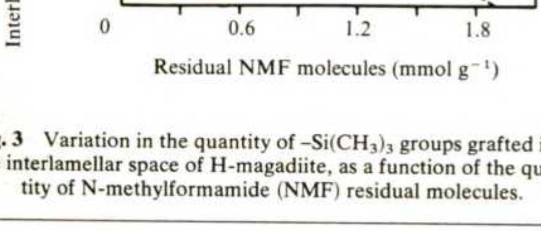

Fig. 3 Variation in the quantity of $-Si(CH_3)_3$ groups grafted into the interlamellar space of H-magadiite, as a function of the quantity of N-methylformamide (NMF) residual molecules.

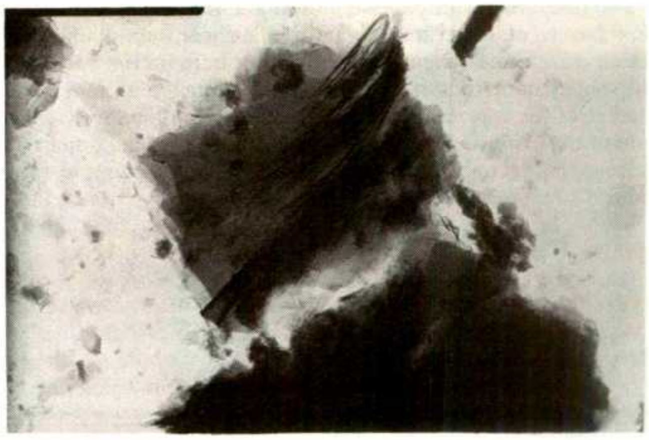

Fig. 4 Microphotograph of a trimethylsilyl derivative of the H-magadiite phyllosilicic acid. Magnification ×75,000.

Chemical analysis and IR spectroscopy show that the progress of the grafting reaction is accompanied by the displacement of the polar organic molecules previously intercalated. The kinetic data show that the rate of grafting reaction of $-Si(CH_3)_3$ groups is equal in absolute value to the rate of desorption of organic polar molecules. Depending on the experimental conditions, a variable quantity of these organic molecules can be trapped in the interlamellar space of the resulting product. The quantity of residual organic molecules (NMF in this case) decreases with the number of $-Si(CH_3)_3$ grafted groups according to a linear relationship (Fig. 3).

The surface covered by grafted $-Si(CH_3)_3$ groups and NMF residual molecules has, in all cases, a constant area equivalent to the calculated area of the interlamellar surface. Chemical analysis and titration of the residual Si–OH groups by NaOH solution can be used to obtain the composition of the resulting materials. For example, in a trimethylsilyl derivative of H-magadiite with a 40% of residual Si–OH groups, the resulting formula can be written as:

$$Si_{14}O_{29}[Si(CH_3)_3]_{1.2}H_{0.8}.0.7\ H_2O$$

where the residual content of organic polar molecules (NMF), as determined by chemical analysis, has been subtracted.

The high thermal stability of these organosilicic materials has been determined by DTA technique. The $-Si(CH_3)_3$ grafted groups remain unaltered until 400 °C.

No important textural changes are observed by electron microscopy when the phyllosilicic acids have been grafted. The planar morphology of the resulting organosilicic materials is shown in Fig. 4, where some corrugation can be seen which could be attributed to the effect of the $-Si(CH_3)_3$ groups grafted on the surfaces of the lamellae.

Table 1 Effect of the interlamellar $-Si(CH_3)_3$ grafting groups on the basal spacing of some typical phyllosilicic acids

Phyllosilicic acid (dehydrated phase)	d_{001} (Å)	Trimethylsilyl derivative d_{001} (Å)	Δd (Å)
α-$H_2Si_2O_5$	7.6	16.2	8.6
$H_2Si_8O_{17}$	16.5	24.4	7.9
$H_2Si_{14}O_{29}$*	11.2	19.4	8.2

* H-magadiite.

The results described above show that it is possible to obtain a new family of macrcmolecular organosilicon compounds, in which the chemical composition depends both on the nature of the starting materials and on the experimental conditions. One feature of these materials is that they maintain the layer structure of the original silicic substrate, but have surface properties corresponding to the organic groups attached, for example, they exhibit a marked organophilic character.

An electrical model of the crust and upper mantle in Scotland

V. R. S. Hutton, M. R. Ingham & E. W. Mbipom

Department of Geophysics, University of Edinburgh, Mayfield Road, Edinburgh EH9 3JZ, UK

Magnetotelluric and magnetovariational studies in southern Scotland[1–4] have been followed by deep electrical soundings at an additional 30 sites. These lie on an approximately linear traverse extending from Kinlochbervie in the Lewisian Foreland to Borthwickbrae in the Scottish Borders (Fig. 1*a*). This traverse crosses the main geological zones of Scotland and follows reasonably closely the line of the LISPB[5] seismic project (Fig. 1*b*). Full details of these geo-electric studies will be published elsewhere. We present here results of two-dimensional modelling of both the magnetotelluric and geomagnetic response functions[6,7] obtained along the traverse.

The model was derived as follows. The digital data from each site were analysed in similar ways to those adopted in refs 8–10. The resulting magnetotelluric response functions, apparent resistivity and phase, were found to be anisotropic at all sites. This indication of lateral variations in conductivity structure was supported by the behaviour of the geomagnetic response functions.

A one-dimensional inversion[11] of the average apparent resistivity and phase data was obtained for each site. These were then used as the basis for applying a two-dimensional modelling programme[12] to each of the sections AA′ and BB′ of the total traverse.

Successive adjustments were then made to the initial two-dimensional models to obtain models which fitted not only both the maximum and minimum apparent resistivity data but also the geomagnetic response functions.

Finally, due to the similarity in the two best-fitting models in the region of overlap to the north of the Highland Boundary Fault, a single geo-electric model was constructed to represent the complete traverse. Observations at Newcastleton and Towhouse[11] have been taken into account to provide a very provisional model across the probable region of the Iapetus suture.

The resulting geo-electric model is given in Fig. 2*a*. This model provides reasonably good agreement between observed and computed response functions for the sites along the traverse marked by arrows in Fig. 1*a*. For traverse AA′, the modelling has been discussed by Mbipom[13] and for traverse BB′ a similar account is in preparation. Here we compare examples of observed and model responses (Figs 3, 4). The model suggests that the electrical structure of the crust and upper mantle in Scotland is, as one might expect from the surface geology, very complex and that there seems to be a distinctive conductivity–depth profile associated with each of the major geological zones along the traverse. For example, the Precambrian fragment to the west of the Moine Thrust is characterized by a resistive crust overlying a less resistive upper mantle, while in the Caledonian metamorphic belt, only the upper 10–15 km of the crust is resistive and the lower crust and uppermost mantle are relatively conducting. The major granitic intrusions are particularly resistive and where the observational density is sufficient the electrical model seems to delineate their form with some success. At the Great Glen, there is a 10 km wide gap in the resistive upper crust where an upper conducting layer connects with the deeper conducting layer of the lower crust and upper mantle. Above average crustal conductivity is also found at shallow depths near the Highland Boundary, Southern Uplands and Stublick Faults. The section of this two-dimensional model covering the south of Scotland confirms and extends the previous one-dimensional interpretation of this region[4]. In the Southern Uplands, the crust is resistive to a depth of ~20 km, and overlies a highly conducting layer, $\sigma \approx 2 \times 10^{-2}\ \mathrm{S\,m^{-1}}$, of poorly defined thickness, 30–70 km. Observational data from the Midland Valley and Northumberland Basin are sparse but in both regions a good conductor exists in the upper crust and it overlies a more resistive layer with the interface between them shelving rapidly near the boundaries of these regions.

This Scottish electrical model can be compared with deep electrical soundings in other countries. Jones and Hutton[4] have already noted the similarity in the conductivity–depth profiles in

MT, Moine Thrust; GGF, Great Glen Fault; HBF, Highland Boundary Fault; SUF, Southern Uplands Fault; NB, Northumberland Basin. (Figure 2*b* from ref. 5.)

the Southern Uplands and in the Canadian Appalachians, regions of common geological history. Further comparison of the Scottish model and that obtained from the Canadian study[14] for a traverse from the Grenville Province of the Canadian Shield to the Appalachians shows another common feature. The electrical conductivity of the lower crust in the neighbourhood of the St Lawrence river, that is the Logan line, where the basement was formed during the Grenville orogeny, is similar to that around the Great Glen, 5×10^{-3} S m^{-1}. In fact, a conductivity–depth profile consisting of a resistive upper crust, a more conducting lower crust and uppermost mantle and a relatively resistive upper mantle seems to be the most common profile in stable continental regions[15–24].

The average conductivity of near-surface continental crustal rocks is generally accepted to be in the range[25] 10^{-5} to 10^{-3} S m^{-1}, as found in the Scottish study along much of the traverse. In some locations, however, the conductivity within the top few kilometres is as high as 10^{-2} to 10^{-1} S m^{-1}. Conductivities of this order of magnitude have been found to be associated with the presence of graphitic schists, geothermal prospects or highly conducting fluids in loosely consolidated sediments.

Thus, in general, all sections of the Scottish model have their counterparts elsewhere. The lateral variation in structure over a distance of only 400 km is, however, probably more striking than in any previous study.

The only published model of the deep structure across Scotland, other than those inferred from studies of surface rocks, is that provided by the LISPB seismic study (Fig. 2*b*).

There is only partial agreement between the geometries of the seismic and electric models. For example, in the Lewisian, the boundary between the resistive crust and more conducting upper mantle occurs at a depth which corresponds well with the Moho as deduced from the seismic study. Further south, however, there is no boundary in the electrical model at Moho depths, but rather a boundary between the resistive upper crust and the more conducting lower crust. This boundary agrees reasonably well with the depth of the Conrad discontinuity. Sharp changes in depth of seismic boundaries, for example, at the Great Glen Highland Boundary and Southern Uplands Faults have their counterparts in the electrical model. The existence of a resistive crust of thickness about 20 km in the Southern Uplands is compatible with the absence of a seismic horizon at 10–15 km depth and a very good conductor in the uppermost mantle is compatible with the absence of a clearly defined signal from Moho depths.

Oxburgh *et al.*[26] have used a schematic crustal model to explain their UK heat flow data. They propose that the variation in heat flow is due to variation in crustal heat production, with the higher heat flow belts including a higher proportion of granites than elsewhere. They require the granites to have a thickness of 16.6 km which is in reasonable agreement with that indicated for the Cairngorm granites in the geoelectric model.

The interpretation of the electrical model will be discussed in detail elsewhere. Here we briefly consider possible explanations of anomalously high conductivity. In the upper crust, it can arise, primarily, as a result of electrolytic conduction in pore fluids, of abnormally high temperature or of intense mineralization. Note that, along the Scottish traverse, the most conducting surface layers coincide with known sedimentary basins in which above average heat flow has recently been reported[26]. The relative contribution of porosity, salinity and temperature in these regions could thus be of interest to the UK geothermal programme. Moreover, similar electrical soundings might be useful to current studies of the deep sedimentary basins in England, especially as pore fluid data are already available from those regions[27].

In the lower crust, the increased pressure and hence crack closure make it unlikely that conduction in electrolytic pore fluids can account for the presence of a conducting zone at this depth. Solid conduction in dry rocks also seems improbable as extremely high temperatures—greater than 700 °C—would be required to provide conductivities of the order of magnitude found in this study. On the other hand, solid conduction through hydrated rocks may be a possibility. Laboratory measurements have also indicated that time-dependent increases in conductivity of up to four orders of magnitude can occur in the solid state due to phenomena such as order–disorder in crystals and rocks[28]. The presence of hydrated rocks with or without associated partial melting has, nevertheless, been the most frequent interpretation for conducting layers in the lower crust[15–24].

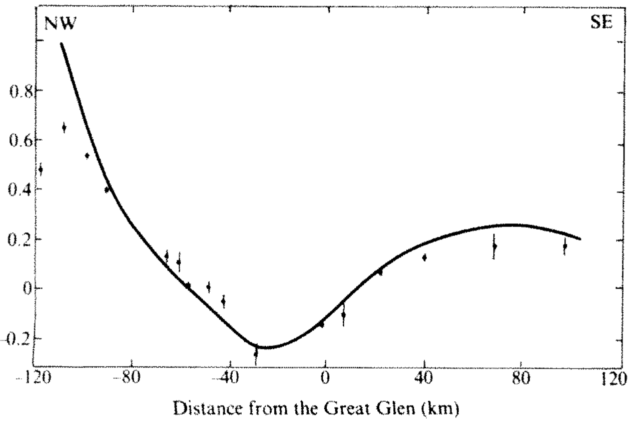

Fig. 3 The variation across the traverse AA′ of the vertical magnetic field transfer function Real (Z/Y), that is the E-polarization case, for a period $T = 95$ s. The solid curve represents the values computed for the model given in Fig. 2*a*. The dots and associated error bars refer to values computed from field data.

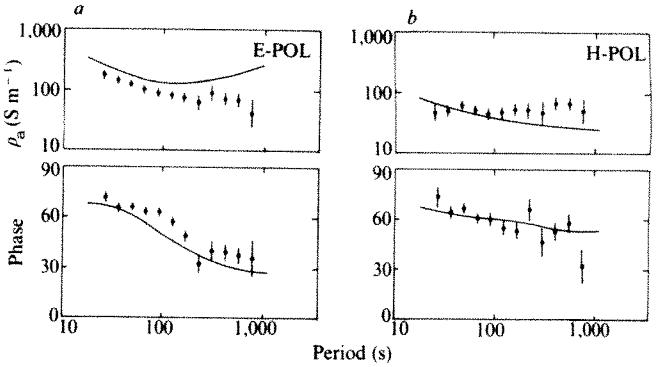

Fig. 4 Apparent resistivity and phase versus period data and associated errors for Yarrow in the Southern Uplands—the station on the traverse BB′ immediately north of BOW in Fig. 1. Curves *a* and *b* correspond respectively to the E and H polarization cases and the smooth curves to the computed values for the model given in Fig. 2*a*.

For example, Berdichevsky *et al.*[18] have discussed the increase in electrical conductivity of granite and other rock types on melting in the presence of water at temperatures of 400–600 °C. They have associated the zone of active granitization and melting with the transition zone between amphibolitic and granulitic facies, that is with the Conrad discontinuity, with the necessary few per cent of water being released as a result of the dehydration at this boundary. Stanley *et al.*[23] have used laboratory results[29–32] to argue that hydrated rocks, such as granite, tonalite, syenite and gabbro, in the upper crust will start melting at 500 °C, especially where the rocks have been subjected to rapid alteration processes. The 500 °C isotherm is, in this case, coincident with a large change in electrical conductivity.

The interpretation of the lower crustal conductor in Scotland in terms of hydrated rocks and partial melting and the other interpretations will be considered elsewhere. However, note that if the granites in Scotland are uranium enriched as in Cornwall and northern England, then a temperature gradient of 30 °C km^{-1} and a depth to the 500 °C geotherm of ~16 km can be expected.

In consideration of Fig. 2*a*, note that: there can be some trade-off between interface depth and conductivity; use of closer station spacing and broader-band electrical soundings may introduce significant changes to the model in some regions; and careful assessment of the validity of laboratory studies is required before further conclusions can be drawn.

It is unfortunate for the tectonic implications of the model that more electrical soundings have not been undertaken in the Midland Valley. If, however, the major boundaries in conductivity structure now suggested to the north and south of this region were confirmed an interpretation of these lateral variations would be possible in terms of former subduction zones as has been suggested in similar studies elsewhere (see refs 33–35). The location of a subsequent subduction zone and the nature of the Iapetus suture[36] may become clearer on the completion of current analyses of geomagnetic and geo-electric observations from northern England.

We thank the NERC for a research grant (GR3/2141) and a studentship for M.R.I., and the Federal Government of Nigeria for a studentship for E.W.M.

Parental magma to the Bushveld Complex

G. Davies*, R. Grant Cawthorn*, J. M. Barton Jr† & Merryl Morton*

* Geology Department, University of the Witwatersrand, 1 Jan Smuts Avenue, Johannesburg 2001, South Africa
† Bernard Price Institute of Geophysical Research, University of the Witwatersrand, 1 Jan Smuts Avenue, Johannesburg 2001, South Africa

The Bushveld Complex of South Africa is a large layered intrusive suite of cumulate rocks for which the parental magma is not directly obtainable. However, we report here indirect evidence from a suite of fine-grained sills in the sediments below the Bushveld Complex. Mineralogical, geochemical and experimental petrological data are consistent with their being representative of the parental magma. They are siliceous picrites ($SiO_2 = \sim 55\%$; $MgO = \sim 12\%$), high in Cr, Ni, Rb and K, and with a high initial Sr^{87}/Sr^{86} ratio, and hence represent a rather unusual magma composition. Crustal contamination may have been important in their evolution.

The layering and mineralogical variation in the Bushveld Complex, shown in Fig. 1, is accepted to be the result of fractional crystallization from a basic magma. However, the exact composition of this magma has been debated. Willemse[1] believed it to be similar to the voluminous metamorphosed gabbroic sills found in the sediments forming the floor to the Bushveld Complex; and suggested contamination of this liquid produced the noritic sills also found in the floor rocks. Typical analyses of these two suites of sills are given in Table 1.

Daly[2] and Wager and Brown[3] studied fine-grained border facies which they believed might be original liquid compositions. Chemically, both are very similar to that proposed as the parental liquid to the Skaergaard Complex (see Table 1), which is surprising as the crystallization sequences and mineral compositions of the two complexes are quite different (Fig. 1).

Vermaak[4] and Hamilton[5] calculated a magma composition using modal proportions from the various zones based on an hypothesis of a new magma injection below the critical zone. Hamilton[5] believed the MgO content of the parental magma exceeded 21% whereas Vermaak[4] regarded it as having komatiitic affinities.

Beneath the Bushveld Complex to the east of Rustenburg, Transvaal, we have identified a suite of micropyroxenitic sills. These intrude the metamorphosed Silverton and Vermont shales and Magaliesberg quartzite of the Transvaal Supergroup[6], and are found from 2 km below to the margin of the complex. They range in thickness from 3 to 10 m. Hopper and branching olivine and abundant bladed to feathery orthopyroxene are present. The matrix is devitrified glass which contains occasional microlites of plagioclase and possibly clinopyroxene (see Fig. 2). These have been described in more detail elsewhere[6]. The crystallization of a small proportion of olivine, followed by a large amount of orthopyroxene, is consistent with the first-formed cumulates of the Bushveld Complex (Fig. 1) and so these sills could represent offshoots of the parental magma.

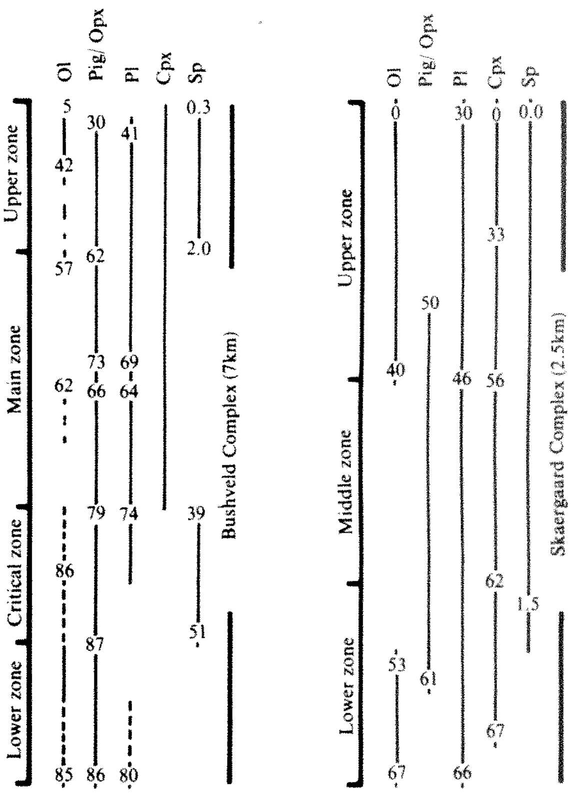

Fig. 1 Crystallization sequences and average mineral compositions in Bushveld and Skaergaard Complexes, from various sources[3,9,16–20]. 100 Mg/(Mg + Fe) ratios for mafic minerals and An content of plagioclase are shown; dashed lines indicate sporadic appearance of cumulus phases. For the spinels, the V_2O_5 contents are shown, except for the minerals near the base of the Bushveld Complex, where numbers refer to the Cr_2O_3 contents.

This suite of rocks is unusual in displaying high SiO_2 content (53–56%) and high MgO (9–13%) and has a Rb/Sr ratio of 0.15–0.20 (Table 1). It also has high K_2O, Ni and Cr.

We have studied several samples experimentally at 3 kbar pressure, one being from the chilled margin of a 3-m sill, occurring 600 m below the Bushveld Complex[7]. It has the second highest magnesium content of the samples analysed (analysis 1, Table 1) but its very fine-grained nature argues against any cumulus enrichment. Phase diagrams at 3 kbar pressure were constructed from our results (Fig. 3*a*, *b*); these are thought to be applicable to the crystallization of the Bushveld Complex. The composition of the chilled margin plots just within the olivine primary phase field in Fig. 3*a* and in the orthopyroxene primary phase volume in Fig. 3*b*.

The likely path it would follow during fractional crystallization is given on Fig. 3*b* by 1–A–B, involving olivine, orthopyroxene, orthopyroxene plus plagioclase, orthopyroxene plus plagioclase plus clinopyroxene. This crystallization sequence is very similar to that observed for the Bushveld Complex (see Fig. 1).

Trace element contents can also be compared with that expected of the parental magma to the Bushveld Complex. Hart and Davis[8] found the partitioning of nickel between liquid and olivine to be dependent on the MgO content of the liquid. For a MgO content of 12.5% a value of $D^{\text{ol}}_{\text{liq}}$ of 9 is obtained. The average NiO content[9] of the lower zone olivine varies between 0.31 and 0.35%. Assuming that those are the first-formed

minerals, the nickel content for the parental magma should be between 270 and 305 p.p.m., consistent with the data in Table 1.

Chromium partitioning between liquid and orthopyroxene is dependent on temperature and oxygen fugacity[10]. Assuming a value of between 1,350 and 1,300 °C for orthopyroxene crystallization temperature[7] and a $\log f_{O_2}$ of -9, a partition coefficient of between 2.5 and 4 is obtained. The average Cr_2O_3 content[9] of the lower zone orthopyroxene is 0.15%, which requires an original liquid with between 874 and 1,399 p.p.m. chromium. Again the data for these sills fall within this range.

The Rb/Sr ratio of the initial magma to the Bushveld Complex has been calculated from partition coefficients[5] as being in the range 0.15–0.25: this is much higher than most basaltic liquids which vary between 0.01 and 0.05. The data in Table 1 show that these sills have this unusual value for the Rb/Sr ratio. The initial $^{87}Sr/^{86}Sr$ ratio, determined by Hamilton[5], for the parental magma is 0.7056.

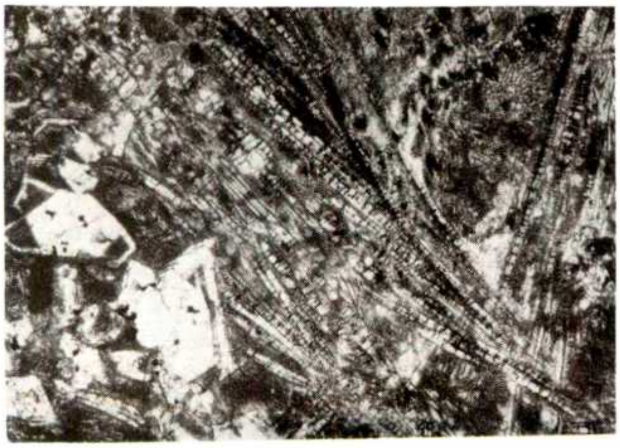

Fig. 2 Photomicrograph of bladed orthopyroxene embedded in very fine-grained matrix of devitrified glass. Hopper olivine crystals present in lower left of photograph. Field of view of the photomicrograph is 0.3 by 0.2 cm.

We have attempted to date an 8-m sill (Table 1, analysis 4) which has a moderate range in Rb/Sr ratios. The data do not define an isochron, but assuming an age[5] of 2,095 Myr, the range in initial $^{87}Sr/^{86}Sr$ ratios is 0.7037–0.7098 with an average of 0.7067. Although more work will be required in this respect it does at this stage support the data of Hamilton[5] and indicates a parental magma anomalously enriched in radiogenic Sr. This, when considered with the high concentrations of SiO_2, K_2O and Rb in such a magnesian magma, suggests that crustal contamination may have been a factor in the genesis of this suite of sills.

The new experimental data[7] mean that previous ideas can now be reassessed. Figure 3 shows a typical gabbro composition (given in Table 1), believed[1] to be the parental magma. The two phase diagrams show the composition plots very close to the

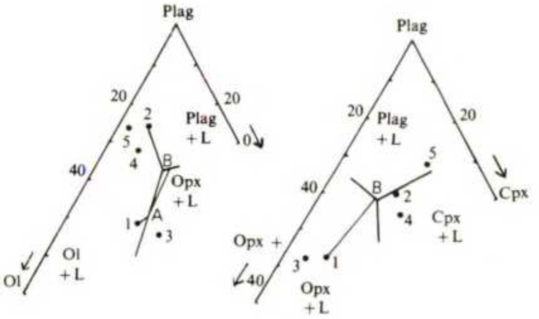

Fig. 3 Phase relationships at 3 kbar pressure from ref. 7 using the projection procedure of Irvine[13]. *a*, Clinopyroxene projection into the system olivine-plagioclase–quartz in cation proportions. *b*, Olivine projection into the system clinopyroxene–plagioclase–orthopyroxene + 4 quartz. The trend 1–A–B in the crystallization sequence is discussed in text. Sample numbers: 1, proposed Bushveld parental magma (analysis 1, Table 1); 2, typical metamorphosed gabbroic sill[1] (analysis 8, Table 1); 3, typical noritic sill[1] (analysis 9, Table 1); 4, proposed parental magma of the Bushveld Complex[3]; 5, proposed parental magma to the Skaergaard Complex[3,21].

olivine, clinopyroxene, plagioclose cotectic and as such will not crystallize the assemblages found for the Bushveld Complex (Fig. 1). Willemse's[1] other contention, that the norite rocks were derived from the gabbro liquid by contamination with siliceous sedimentary material, is questionable as the typical noritic composition (see Table 1) contains higher MgO than the gabbro, and so cannot possibly result from contamination of the latter.

Experimental studies at 1 atm pressure on Wager and Brown's[3] sample gave a different crystallization sequence[11,12] from that found in the Bushveld Complex, and Biggar[12] therefore rejected this as the parental magma. Daly's[2] sample was also studied by Tilley *et al.*[11]: they were dubious about its being the parental magma to the Bushveld Complex as it also gave a different sequence to that observed in the Complex as a whole. Irvine's[13] suggestion that possibly at higher pressures Wager and Brown's[3] sample could produce the right crystallization sequence is not consistent with the phase diagrams in Fig. 3, where the early crystallization of clinopyroxene is implied. The calculations of Vermaak[4] and Hamilton[5] have been questioned by Von Gruenewaldt[14] as the areal extent of the zones is a matter for speculation. Obviously the results of such a calculation would be very dependent on the shape of the complex. If the complex is funnel-shaped as evidence cited by Button[15] and Cameron[9] suggests, then the effect of the lower olivine- and pyroxene-rich (MgO-rich) zones would be overestimated in these calculations. The models of Vermaak[4] and Hamilton[5] are also based on the assumption that there is a new magma influx below the critical zone. Cameron[9] presented detailed mineral analyses across the lower zone–critical zone boundary and concluded there was no evidence for multiple magma injection at this level, at least in the eastern lobe of the Bushveld Complex.

None of the proposed parental magmas of Willemse, Daly, Wager and Brown, Vermaak or Hamilton seem very plausible, while the composition presented here seems in many respects to be consistent with the constraints required for it to be the parental magma to the Bushveld Complex.

Financial support from CSIR (South Africa) towards this research project is acknowledged.

Fossil carbon in coastal sediments

M. S. Baxter, M. J. Stenhouse & N. Drndarski

Chemistry Department, University of Glasgow,
Glasgow G12 8QQ, UK

Fossil carbon, as present in coal, oil and their derivatives, is free from radioactive ^{14}C and its presence in even small concentrations within sedimentary materials can lead to anomalously old radiocarbon ages. For example, Erlenkeuser *et al.*[1] have noted artificially high ^{14}C ages in the upper 20 cm of Baltic Sea sediments in correlation with enhanced heavy metal concentrations. Both findings are consistent with the growth of industrial activity in this location, and the radiocarbon age increase has therefore in the past been regarded as an approximate measure of the extent of pollution of sediment organics by industrial fossil fuels. The results presented here will indicate that the latter interpretation is not always valid and that in studies of coastal marine sediments the incorporation of natural fossil carbon in the samples can introduce considerable error.

Surface sediments from the Clyde Sea area in south-west Scotland were analysed and their radiocarbon data compared to those reported by other workers (ref. 2 and D. D. Harkness, personal communication) (Table 1). These sediments were brown muds of silt-clay composition and had carbon contents typically around 5% on a dry weight basis. In each case these surface deposits were known to have accumulated during the twentieth century, their radiocaesium and ^{210}Pb contents having been monitored[3]. From each sample, inorganic carbonaceous matter, normally comprising ~1.8% of sediment dry weight, was removed by hydrolysis in hot 15% HCl for 2 hours. It is the residual component—the acid insoluble organic fraction—which is being discussed here. Radiocarbon analysis was performed by either CO_2 gas proportional or C_6H_6 liquid scintillation techniques using conventional methodology[4,5] and the radiocarbon dates are reported in the normal way[6], using the 5,568-year Libby half-life value. For the data presented in Table 1, the standard deviation associated with analysis is normally of minor significance relative to the age differences under discussion but in all cases is less than ±200 yr. The principal observation from the data is that surface ^{14}C ages are extremely large relative to the idealized near-zero values which should apply. There is therefore a significant concentration of fossil carbon present. This in itself is scarcely surprising given that the Clyde marine system receives major inputs of both industrial and domestic organic wastes from the Glasgow connurbation and surrounding regions[7]. While there is some localized variability in ^{14}C age distribution, the general ^{14}C age trend shown in Table 1 can be reasonably interpreted as reflecting the corresponding degree of pollution exposure, with sites nearest industrial releases having oldest ^{14}C ages. At the two extremes in the Table 1 data, ages of 1,595 yr (Loch Etive) and 10,490 yr

Table 1 Radiocarbon ages of surficial sediments

Sample	^{14}C age (yr)	Ref.
Loch Etive*	1,595	‡
Loch Goil, core 1	2,320	This work
Loch Fyne, core 1	2,650	2

Garroch Head†	4,120–10,490	2

*Loch Etive result included for comparison only—this site lies outside the Clyde area on the west coast of Scotland.

†Garroch Head, in the inner Firth of Clyde, is the disposal site for Glasgow's domestic/industrial solid waste. ^{14}C ages decreased from 4,120 yr at the surface to 10,490 yr at 30 cm (ref. 2).

‡D. D. Harkness, personal communication.

0028–0836/80/360035—02$01.00

(Garroch Head) correspond to fossil carbon concentrations (in the organic fraction) of ~18% and 73% respectively. At this stage it was tempting to postulate anthropogenic release of fossil carbon as the sole cause of the observed age anomalies.

The set of results which sheds most light on the issue, however, comes from a 3-m long sediment profile at a sampling site in the Arran Deep trench, a location in the outer Firth of Clyde which is considered relatively natural and far removed from organic waste releases. Here the sediment is very fine-grained brown to grey mud of total carbon content ~2%, approximately one third of which is in carbonate form. The latter fraction was removed by acid hydrolysis as before. The results surprisingly show that erroneously old ^{14}C dates are not confined to post-industrial horizons but occur throughout the profile (Fig. 1). That abnormally high ^{14}C ages are obtained even at depth shows clearly that the contaminant there is of natural origin and suggests that, in the recent sediments considered so far, a combination of both natural and industrial fossil carbon inputs is occurring.

Evidence that the deeper section of the Arran Deep core is pre-industrial and that its ^{14}C chronology is misleading comes first from palaeomagnetic marking of horizons which places the 1.75-m level at ~600 yr before present (R. Thomson and G. M. Turner, personal communication). In addition, the ^{14}C age profile is consistent with a pre-industrial period of constant sedimentation rate (between 170 and 260 cm), which by regression analysis of the data in that interval is assessed at 0.6 ± 0.1 mm yr^{-1} (coefficient of correlation, 0.99). This estimate is in good agreement with a previous assessment of 0.3 to 0.6 mm yr^{-1} for a neighbouring location[2]. To a first approximation, the regression line drawn in Fig. 1 can therefore be regarded as the baseline representing the natural ^{14}C age profile at this site. Extrapolation to zero depth shows that the natural ^{14}C age for surficial deposits is ~3,000 yr, corresponding to a fossil carbon content of ~30%. The explanation of the high natural ages must, in our view, involve the natural erosion and inwash of coal dust from the outcrops of coal seams in the Clyde coast and catchment. This postulate is supported by the result of attempts to totally dissolve deep sediment samples in strong acids. In all cases, a fine black suspension of particulates remains, the carbon content of the dried dust being 60 to 70%. The overall abundance of the coal dust is sufficient to produce the observed age anomalies but would not normally be isolated during conventional pretreatment techniques. Thus when an aliquot of sediment, from 250 cm depth, containing 68 mg of organic carbon was exhaustively treated with HF, the residual particulate material was found to contain 26 mg of organic carbon, corresponding to ~35% of the total acid-insoluble organic fraction. Furthermore, the sediment was shown by microscopic examination to be rich in Carboniferous spores and it therefore seems certain that the high ^{14}C ages in Clyde sediments primarily reflect natural coal erosion in the catchment, a process whose effect has not to our knowledge been reported elsewhere and which could induce major dating errors or be relevant to interpretation of dates from many other areas. Certainly, the magnitude of the effect, the chemical inertness and appearance of the contaminant and the presence of Carboniferous spores combine to rule out the possibility that the observed ^{14}C dilution is caused by soil and blanket peat erosion, a process frequently reported elsewhere[1,8–11], being induced by changes in catchment land use.

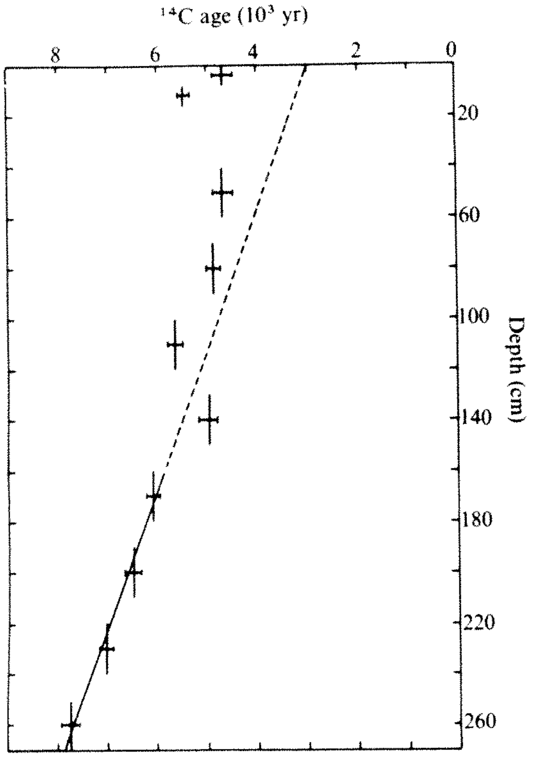

Fig. 1 Radiocarbon age/depth profile in Arran Deep sediments. Horizontal and vertical bars represent the ± 1σ dating errors and sample depth intervals respectively. The straight line is the best fit regression line through the lower data points.

That the upper data points lie to the high-age side of the natural chronology (represented by the straight line) reflects anthropogenic disturbance of the sedimentation pattern. Thus input of fossil carbon by industry and waste dumping further ages the topmost layers and is allied to a much increased deposition rate. While the sampling frequency is insufficient for detailed analysis, it is possible that the uppermost sample is slightly younger through incorporation of artificial ^{14}C released mainly in the 1960s by nuclear weapon tests. In agreement with our interpretation of the ^{14}C profile, ^{210}Pb and radiocaesium analyses (J. Smith-Briggs, personal communication) have shown that the present sedimentation rate is ~20 mm yr^{-1}. The maximum ^{14}C age observed in surface layers (5,450 yr at 15 cm) corresponds to a minimum total fossil carbon contribution of ~50%. Thus at this site the natural fossil carbon contributes 30% and the industrial component 20%.

The results presented briefly here indicate the need to consider natural fossil carbon contamination as a potential and significant source of error in dating sediments. This natural component applies at all sediment depths, and, if constant, does not preclude estimation of deposition rates. In recent surficial samples, however, the natural input is added to and masked by anthropogenic releases. If long cores are not available, the two fossil components cannot be differentiated and considerable errors may arise in evaluating the data. Certainly, in the Clyde Sea area, radiocarbon dating of sediments is dominated by these large fossil carbon effects.

We thank the staff of the Clyde River Purification Board, the Natural Environment Research Council and the crew of the NERC research vessel John Murray for collection of sediment samples. Examination of pollen and spores in the sediment was performed by J. H. Dickson. We also thank D. Thomson and S. Holland for technical assistance.

A model of epicontinental reef growth

Peter J. Davies & J. F. Marshall

Bureau of Mineral Resources, Geology and Geophysics,
Canberra City ACT 2601, Australia

The growth of coral reefs has been a controversial subject ever since Darwin's[1] subsidence theory. Scientists have argued over the major factors affecting growth[2–4], but most have agreed that reefs grow dominantly along their windward margins[5–7], a characteristic displayed in the Permian[8] and Devonian[9] reefs of New Mexico and Western Australia. Recently, however, Adey[10] has indicated that the growth characteristics of windward margins are energy related, such that different growth characteristics are to be expected under different energy regimes. The Great Barrier Reef is a high-energy epicontinental shelf reef system on which it has been suggested[11–13] that, in the prevailing conditions, windward growth has been subordinate to vertical and leeward growth. We present here results from drilling and monitoring studies demonstrating that reef growth in a transgressive epicontinental shelf environment is first vertical and then backwards, especially on the leeward margin, when the reef reaches the stillstand sea level position.

Our main body of data stems from extensive geological studies on and between the reefs of the Southern Great Barrier Reef. Four reefs have been studied in detail, but we report here only the results from One Tree Reef (Fig. 1) where comprehensive and integrated geological[14–17], and biological studies[18–20] have been conducted for 10 yr. Previously reported geological studies on this reef have defined its major physiographical features, relating them to features of the Pleistocene substrate. Thus the present reef rims surmount elevations in the substrate while the present lagoon covers a depression in the Pleistocene surface[16].

The Holocene section of the reef has been cored at six sites (Fig. 1), three near the southern, windward margin (1, 2 and 4), two on the leeward margin (3 and 5) and one on a patch reef in the lagoon (6). The facies variations encountered in four of these holes are shown in Fig. 2, from which the following conclusions are drawn.

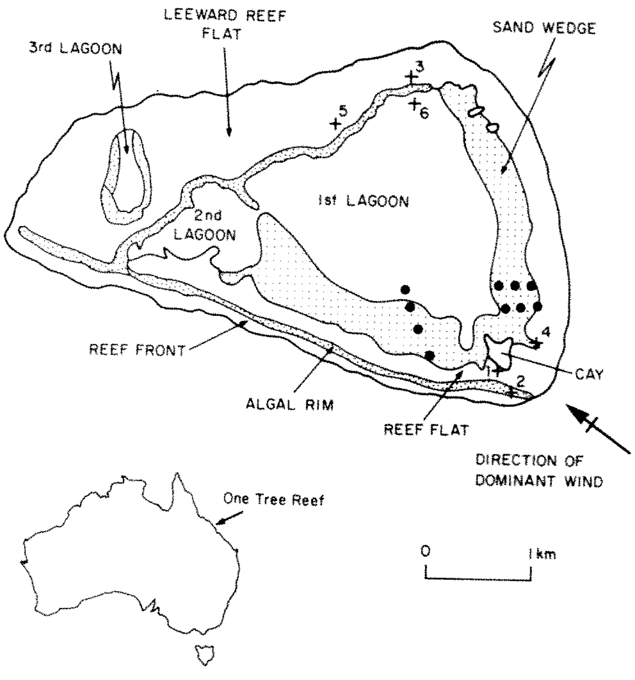

Fig. 1 One Tree Reef: physiographic features and sample sites. +, Drill sites; ●, sediment cores.

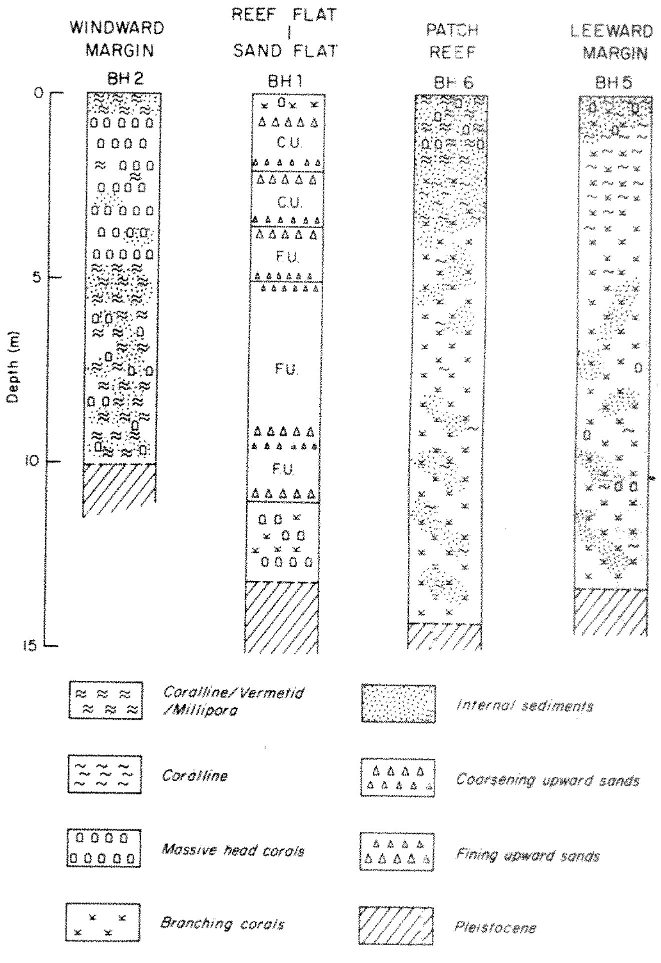

Fig. 2 Stratigraphic sections through Holocene at One Tree Reef, Southern Great Barrier Reef. Drill hole locations are shown on Fig. 1. % recoveries are BH1, 40%; BH2, 95%; BH5, 60%; BH6, 76%.

Growth on the windward margin is dominated by head corals together with a coralline algae/*Millepora*/vermetid assemblage that forms a massive framework (hole 2). The latter assemblage especially dominates the lower section of the drill hole whereas at the surface it forms only thin crusts.

Sands, compositionally identical to and clearly part of the accreting sand wedge (Fig. 1), were encountered to a depth of 11 m in hole 1, drilled at the junction of the reef flat and sand wedge. The lower half of the sand sequences exhibits fining-upward rhythms indicative of episodic storm supply from the reef margin and representing the earliest, deeper subtidal stages of lagoon infill. The upper portions of the sand sequence show a series of coarsening-upward rhythms, representing very shallow subtidal to intertidal accretion. Identical rhythms are seen in vibrocores through the top 5 m of the accreting sand wedge (Fig. 1).

The leeward lagoonal patch reef (hole 6) is surprisingly dominated in the top part of the section by the head coral/coralline algae-*Millepora*-vermetid association, similar to that seen in the windward hole. Porosity is low due to multiple generations of internal sediment. Branching corals predominate throughout the rest of the section.

At leeward sites (hole 5), a much thinner coralline crust with subordinate head corals overlies a dominantly branching coral section forming an open framework.

Radiocarbon dating of corals from three of the boreholes (Fig. 3) shows (1) that growth on windward margins (hole 2) throughout much of the Holocene occurred at a rate of 3.2 m kyr^{-1} except for a short burst in the top part of the section when the rate doubled; (2) that growth on the leeward margins (hole 3) throughout all but the bottom 1.5 m of section was nearly twice as fast as growth on the windward side; (3) that the growing reef reached sea level around 5,000 yr BP on the windward side compared with 1,000 yr BP on the leeward side; and (4) that in hole 1, the slow accretion rate of 1.7 m kyr^{-1} relates to the vertical growth of the accreting sand wedge and correlates well with independent estimates of lagoonal sand accumulation[21,22]. Much of the sand section accumulated only after the windward margin reached sea level, suggesting that little material is shed during the vertical growth phase (Fig. 3).

Growth at the stillstand sea level has been studied by monitoring the relations between calcification and sedimentation. Net calcification estimates at One Tree Reef[18–20] show the windward perimeter zones (algal and coral flat) accreting at a rate of 4 $\mathrm{kg\,m^{-2}\,yr^{-1}}$. Measurements of water and sediment movement show daily losses[23] from the windward algal rim and reef flat of 0.6 and 1.8 kg respectively, this being to leeward, into the lagoon. Similar measurements on the leeward margin indicate differences in sediment transported on neap and spring tides. During neaps, there is a daily excess of 0.6 kg entering the lagoon from the leeward edge whereas during springs, the lagoon water is flushed quickly resulting in an excess of 2.9 kg transported out of the lagoon and over the leeward margin. A conservative estimate would indicate considerably more than 2,000 tonnes of $CaCO_3$ moving over the leeward margin every year. Seismic reflection profiling shows a wedge of sediment, interpreted as Holocene, up to 10-m thick extending 1 km away from the leeward margin (D. Searle, unpublished data).

We conclude that when a reef reaches sea level, growth is markedly influenced by the surface hydrological regime, resulting in lagoonal infill and leeward accretion.

Our data have implications for both growth concepts and reef management. In conditions of sea level rising at a rate greater than the rate of calcification, the dependence of growth on light will give rise to vertically growing structures. These will eventually be drowned if sea-level rise continues to outpace growth. However, if sea-level rise slows or reaches a stillstand position, vertical growth will continue, with little loss through shedding, until such time as the potential accretion exceeds that of sea-level rise. At such time as the hydrological regime imposes its own growth restrictions, accretion will dominate on the leeward margins and the reefs will grow to leeward. That this mechanism also applies to other parts of the Great Barrier Reef is shown by reports from the 1973 Royal Society Expedition to the area[24].

The total growth history of an epicontinental reef system such as the Great Barrier Reef is one of a series of growth phases alternating, during the Plio–Pleistocene at least, with prolonged periods of subaereal exposure. The record will, therefore, consist of a series of reefal and related sediments separated by solution unconformities[25]. If past growth approximates that which has occurred in the Holocene, then the facies patterns produced will resemble those defined in the Holocene, and will differ substantially from those described in the classically accepted models; for example, the windward and leeward directions are reversed. Such a postulate must have important palaeogeographic and mineral exploration significance. Implicit to our model is the understanding that the depth to the Pleistocene substrate determines the time at which the reef reaches sea level and, therefore, the length of time for which changes in the surface zone have occurred. It follows that some reefs may have reached sea level recently, exhibiting few characteristics of leeward accretion: such reefs will contrast with others where lagoons are infilled and where the leeward margin has prograded considerably. We designate reefs which have just reached sea level as juvenile, and those with considerable leeward progradation as senile. One Tree Reef, which is intermediate between senile and juvenile, is described as mature. All reefs in the Capricorn/Bunker Groups of the Southern Great Barrier Reef may be identified in one of these three classes, and we suggest that such a genetically based growth classification may have considerable managerial importance. For example, juvenile and senile reefs may react very differently to environmental perturbations, either natural or man-made.

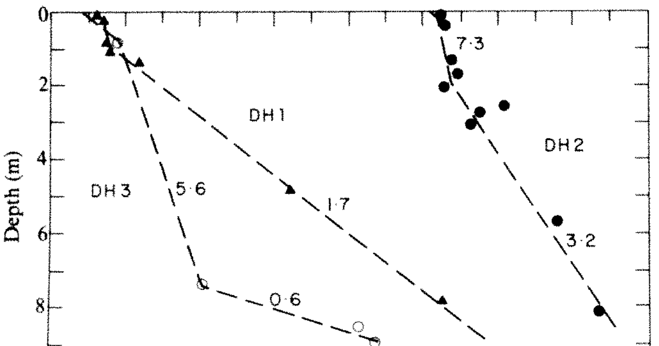

Fig. 3 Rates of reef accretion (m kyr^{-1}) displayed in three boreholes at One Tree Reef. Note that accretion in hole 1 starts only after the perimeter margin (hole 2) has reached sea level around 5,000 yr BP. Only corals in growth position have been dated.

Oxidative changes to nitrate and boron in marine pore waters

Kent A. Fanning & Valentine I. Maynard-Hensley
Department of Marine Science, University of South Florida,
St Petersburg, Florida 33701

Reported changes in the composition of marine pore water on contact with air[1–4] led us to investigate whether air-exposure of marine sediment might alter its interstitial concentrations of nitrate and boron. Nitrate should be a good indicator of changes in the oxidation state of marine sediments[5,6], and interstitial boron should reflect changes in the reactivity of sedimentary components because it bonds to clays[7,8] and sediments in a temperature-sensitive manner. We report here that interstitial nitrate concentrations can increase considerably during air exposure of marine sediment and that interstitial boron can be scavenged from some reducing sediment. Sedimentary boron scavenging may affect oceanic boron, but the process may be influenced by interstitial components that prevent the uptake of boron onto freshly formed hydrous ferric oxides.

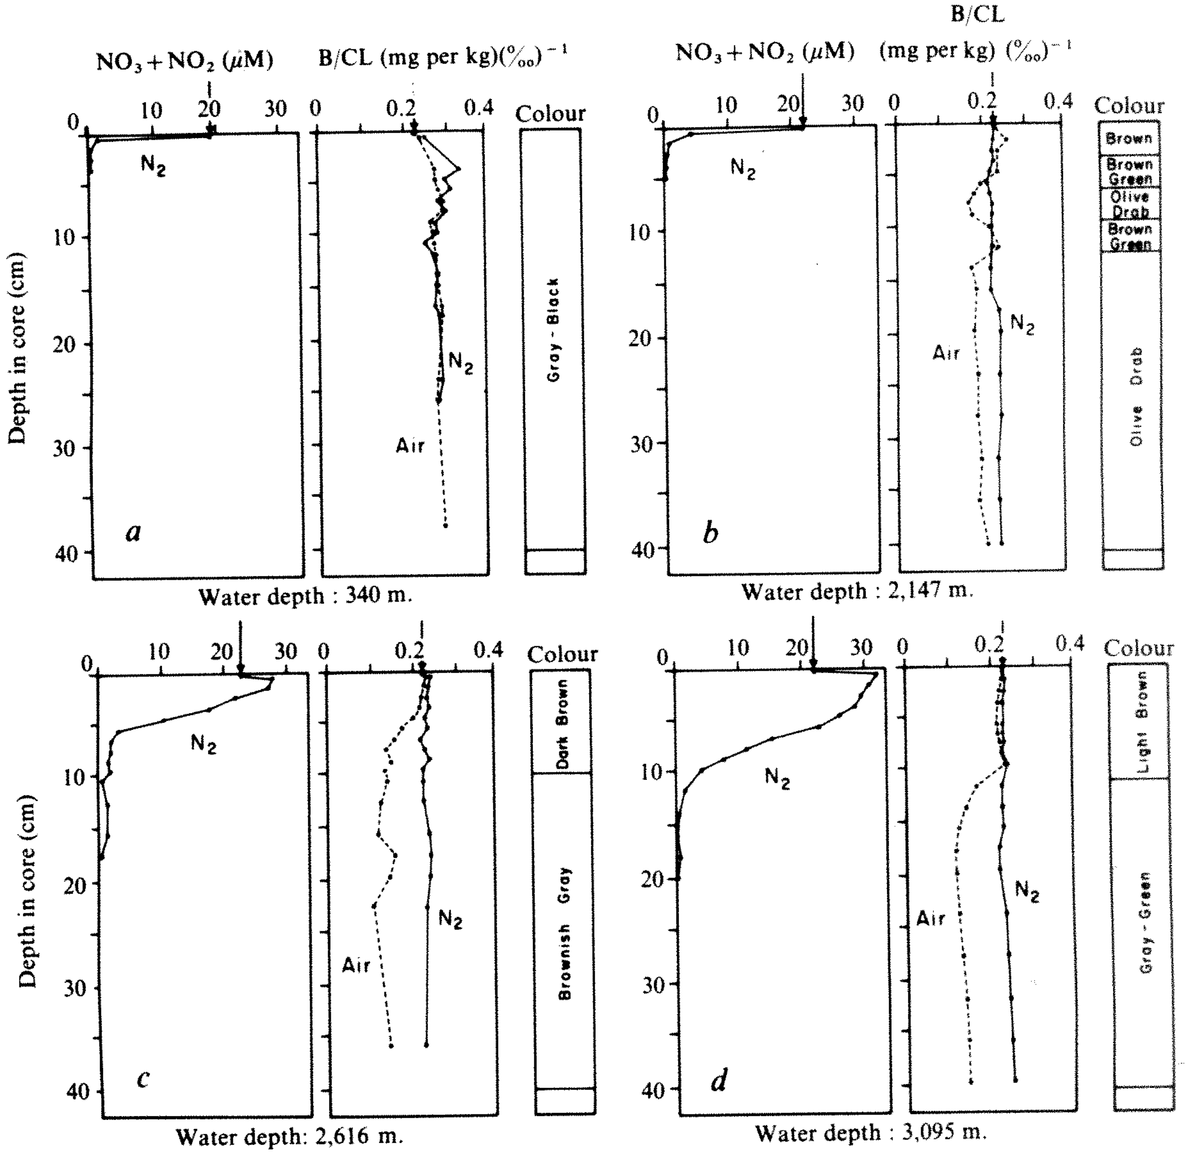

Fig. 1 Air-squeezed (· · · ·) and nitrogen-squeezed (———) profiles of interstitial ratios of boron to chlorinity and interstitial concentrations of nitrate + nitrite in sediments from the delta of the Magdalena River. The arrows indicate values of near-bottom seawater above each core. Colour patterns in the sediment are also shown. A Benthos Model 2171 gravity corer was deployed from the RV Gyre out of Texas A & M University. To minimize disturbance during coring, no cutter, catcher, or barrel was used, and the lowering speed on the winch was less than 20 m min^{-1}. *a*, 340 m water depth; *b*, 2,147 m water depth; *c*, 2,616 m water depth; *d*, 3,095 m water depth.

In August 1977, four 6.5-cm diameter gravity cores were taken from different water depths on the Magdalena River delta near Barranquilla, Columbia (Table 1). Each core was immediately sealed and transferred to a room kept at around the same temperature as that where the core was obtained: 17 °C for the 340-m core and 4 °C for the cores from deeper water (Table 1). Each core was opened and cut into 1-cm slices inside a nitrogen-filled plastic bag at positive pressure. Half of each slice was squeezed to remove its pore water while still inside the bag; the other half was exposed to air for 1–2 h and then squeezed to extract its pore water in oxygenating conditions. For each core, the processing temperature was the same as its storage temperature.

Air-squeezed and nitrogen-squeezed pore waters were analysed for dissolved boron[10], for dissolved nitrate and nitrite[11], and for chlorinity using $AgNO_3$ with dichlorofluorescein as endpoint indicator. Air-squeezed and nitrogen-squeezed profiles for each core were compared to each other and to the core's colour pattern (Fig. 1*a–d*).

Air-exposure of Magdalena sediment produced strong enrichments in interstitial nitrate + nitrite (Table 2). The increases were usually confined to the upper parts of the cores, and the largest were in the upper 4 cm of the core from 2,616 m of water. The zone seemed to be reasonably oxidizing because of its high initial concentrations of nitrate and because of its dark brown colour[12]. Air exposure did not produce large enrichments in sediment which was so reducing that nitrate or nitrite was originally absent. (Possibly the microorganisms whose metabolism might be stimulated by air are not likely to be important in such sediment.) Thus conclusions based on nitrate data from air-exposed sediment may be suspect, even for deeper-water deposits thought to be oxidizing. Also, atmospheric contact may stimulate nitrate production in tidally exposed sediment.

Figure 1 shows only nitrogen-squeezed profiles of nitrate + nitrite for comparison to the profiles of air-squeezed and nitrogen-squeezed interstitial boron. For most of the Magdalena cores, interstitial nitrite concentrations were small (around 0.2 μM), and we will consider only nitrate here.

Figure 1 shows the boron–chlorinity ratios (B/Cl) in the pore-water samples. The conservative nature of oceanic boron means that all results may be compared with the typical value of the ratio: 0.23 (mg B per kg) (‰)$^{-1}$ (see refs 13, 14).

The Magdalena profiles show that interstitial boron can be strongly scavenged from marine pore fluids when atmospheric oxygen penetrates the exposed sediment. In two cores from deeper water (Fig. 1*c*, *d*), interstitial boron–chlorinity ratios were reduced by as much as 50%, indicating a consumption of 210 μM borate or 2.2 mg B per kg of pore water. In the third deeper-water core (Fig. 1*b*), the loss was less. In the shallowest core (340 m, Fig. 1*a*) the ratios were slightly higher than normal, probably because the room in which the 340 m core was processed was a little too warm at 17 °C. Seawater temperature at 340 m was 12 °C, and a 5 °C increase should cause interstitial boron concentrations to rise detectably[9].

No zone showing strong scavenging of boron contained much nitrate. Air-sensitivity of interstitial boron was most likely when the sediments were so reduced that interstitial nitrate was 5 μM or less. When nitrate concentrations were higher, a solid phase capable of removing boron was apparently absent or too oxidized to function.

Actual scavenging phases in reducing zones could have been freshly precipitated forms of Fe(III) which were created when atmospheric oxygen reacted with Fe(II) that was either dissolved in pore water or attached to particle surfaces[1-3]. In cores from water deeper than 2,000 m (Fig. 1*b–d*), zones of sediment that showed no scavenging of interstitial boron had brownish colours, suggesting that Fe(III) dominated over Fe(II) in the solid phases[12]. However, intensity and distribution of boron scavenging varied considerably in the four Magdalena cores. Organic matter in the sediment may influence the degree of scavenging because of the affinity of borate for carbohydrates and other organic compounds with alcohol groups[15,16].

The uptake of oceanic boron by iron compounds was studied by using two laboratory simulations of the action of sedimentary ferrous iron during air exposure at 4 °C. In both, 500 ml of pelagic seawater was enriched with 'scavengeable' nutrients until the initial concentrations were 200 μM silica and 20 μM phosphate—values often found in reducing marine pore waters[3]. Initial boron concentrations were 406 μM (4.29 mg B per kg seawater) in the first experiment and 418 μM (4.42 mg B per kg seawater) in the second. To inhibit the oxidation of Fe(II), the enriched batches of seawater were bubbled with nitrogen for 2 h to remove dissolved oxygen and then acidified to *p*H 3 with concentrated H_2SO_4. $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ was added to each flask to make its acidified seawater 13,000 μM in dissolved Fe(II) so that there was initially a 20 : 1 molar ratio of ferrous iron to total scavengeable solutes (silica + phosphate + boron). In the second experiment, the seawater was also made 20,000 μM in mannitol to see if a large amount of boron-complexing organic matter altered the scavenging of boron. Then, over a 2-h period, oxidative scavenging was induced by adding concentrated NH_4OH dropwise while stirring and bubbling air into the flasks. As the first drops of NH_4OH entered the seawater, a bluish precipitate formed which eventually turned red-brown as air bubbles mixed with it. Towards the end of each experiment, the drops of NH_4OH produced more red-brown precipitate directly with no bluish intermediate. Addition of NH_4OH was stopped when the *p*H passed 8.5 and dissolved iron was less than 3% of its initial value. The reaction flasks were polythene.

Table 1 Data on cores from the Magdalena Delta

Core no.	Water depth (m)	Position
77-G-8, G.C. 2	340	11°08.4′ N, 74°54.8′ W
77-G-8, G.C. 8	2147	11°23.5′ N, 75°25.3′ W
77-G-8, G.C. 7	2616	11°39.5′ N, 75°33.5 W
77-G-8, G.C. 6	3095	11°49.5′ N, 75°38.1′W

Final aliquots were removed from the two batches of seawater, filtered through 0.4 μm Nuclepore membranes, and analysed. The dissolved silica and phosphate initially present in both experiments were at least 98% removed. In the first experiment, the boron–chlorinity ratio was 12% lower after the precipitation of Fe(III) hydroxide was finished. However, in the second experiment, the added manitol apparently restricted the scavenging of boron because the final boron–chlorinity ratio was only 2% less than the initial ratio.

There are two curious features of the Magdalena data (Fig. 1): (1) interstitial nitrate was absent or nearly absent from any sediment in which a sizeable air-induced uptake of interstitial boron occurred, and yet (2) the absence of nitrate did not guarantee an air-induced uptake of boron, for example in most of the 340 m core and in parts of the upper 12 cm of the 2,147 m core.

The laboratory simulations provide partial explanations. Freshly oxidized and precipitated Fe(III) oxide did scavenge boron from seawater along with silica and phosphate. Marine sedimentary Fe(II) that can form fresh Fe(III) oxides is apparently not present until interstitial nitrate has been consumed by reduction reactions[17]. Therefore, air-induced

boron scavenging and nitrate could be mutually exclusive in sediments. However, our experiments did not display the extensive boron losses found in much of the deeper Magdalena sediment. Perhaps insufficient Fe(II) was used compared with that available in sediments, or the surface area of sedimentary particles may be important. But the lack of boron scavenging in some reducing sediments is more puzzling. The simulations suggest that interstitial organic matter may have been responsible. Although mannitol is not a major organic compound in sediments, it has been reported for marine cores[18], and we found that it hampered the scavenging of boron by Fe(III) oxides. It probably did not drastically alter the surface properties of the Fe(III)–oxide precipitates because silica and phosphate were scavenged with or without mannitol. Therefore, the mannitol may have complexed the boron so that it was not scavenged as effectively. Similar 'protective' complexation between boron and sedimentary organic compounds may occur in natural reducing sediments. In fact, a weak response of interstitial boron to air exposure may be an effective indicator of the presence of such compounds in a sediment.

Marine sediment can encounter elemental oxygen in two forms: an atmospheric gas or an oceanic solute. Our results suggest that this encounter could stimulate reactions which become important parts of the cycles of nitrate and boron in the sea.

We thank Lynn J. Burton and Jabe A. Breland for careful processing of sediment under adverse cold-room conditions. We also thank the office of Naval Research (Contract N00014-75-C-0539) and the NSF (OCE76-82416) for financial assistance.

Records of *Cooksonia*-type sporangia from late Wenlock strata in Ireland

D. Edwards

Department of Plant Science, University College, Cardiff CF1 1XL, UK

J. Feehan

Department of Geology, Trinity College, Dublin 2, Ireland

Hitherto the earliest record of a fossil flora containing *Cooksonia* type sporangia was from a mid-Ludlow (Silurian) locality in Wales[1]. The compression fossils illustrated here (Figs 1–4) come from strata assigned to the highest graptolite zone of the Wenlock Series characterized by *Monograptus ludensis*. They were collected (by J. F.) in the Devilsbit Mountain district of County Tipperary, Ireland. But this is not just a record of the first appearance of a genus which extends to the end of the Lower Devonian, because *Cooksonia* has generally been accepted as a vascular plant[2]. Its occurrence at the top of the Wenlock therefore seems to extend the history of vascular plants back to the middle of the Silurian and to indicate that higher plants colonized land surfaces at least 415 Myr ago.

The very fragmentary plant fossils are scattered among numerous irregular patches of coalified material, the rock matrix being a slightly micaceous buff siltstone interlaminated with a grey-green mudstone from which fossils are absent. In marked contrast to later Ludlow records, sterile branching axes of *Hostinella*-type are rare and far outnumbered by the fertile specimens. One of the latter, which exhibits dichotomous branching, is shown in Fig. 1. The sporangia are tangentially extended and oval to irregular in outline. They most closely resemble *Cooksonia pertoni* Lang, but are considerably smaller. We have illustrated the remaining specimens to show some of the range in sporangial morphology, which indicates that more than one morphospecies is represented. As they are subtended by very short lengths of unbranched axis, they do not strictly conform to the generic diagnosis of *Cooksonia*, although one of them (Fig. 4) is similar to *C. hemisphaerica* Lang in sporangial shape.

However, because we have not yet seen tracheids on cellulose acetate film pulls taken from these Irish compression fossils, we cannot be absolutely certain that they were vascular plants. Had they been found in later, for example, Downton (Pridoli) or

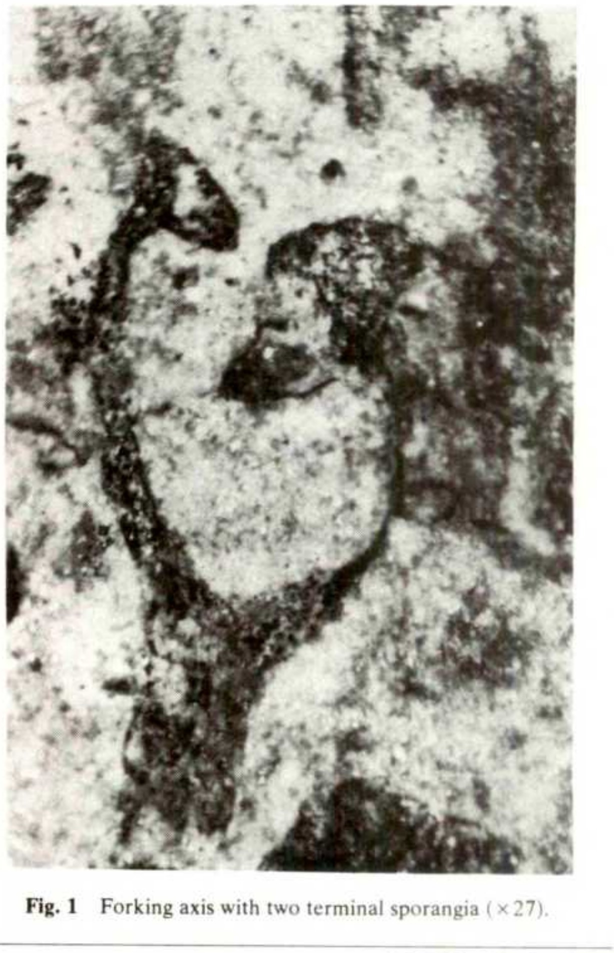

Fig. 1 Forking axis with two terminal sporangia (×27).

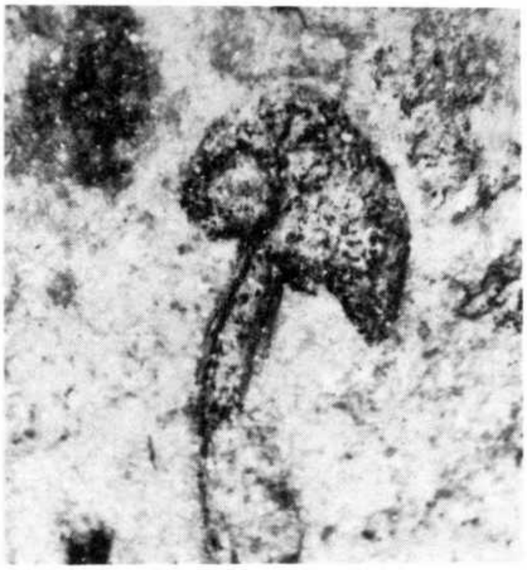

Fig. 2 Terminal sporangium (×25).

Gedinne sediments, such fossils would undoubtedly be assigned to *Cooksonia* and be accepted as vascular plants. In view of their great stratigraphical age and their relevance to such highly controversial issues as the ancestry and origin of vascular plants, the possibility that the Irish fossils had identical morphology to *Cooksonia* but lacked conducting tissues cannot be ignored. Pratt *et al.*[3] described such a level of organization as rhyniophytoid. Sterile branching axes lacking vascular tissues and thought to belong to erect plants have been reported from early Silurian deposits in the United States[4]. The authors of that report suggested that the plants were "representatives of primitively emergent vegetation" (page D71) and "incipient vascular plants" (page D72). In a different physiological approach, Raven[5] argued that the alga-vascular plant intermediate would require a plant body of some size in order to release its meiospores into air currents and that such spores with sporopollenin-impregnated walls would be produced at the apices of parenchymatous axes. Similarly Smith[6] raised the possibility that the parent plants of the simple, smooth-walled spores with triradiate marks which he has isolated from Wenlock strata in County Mayo were non-vascular aquatics (? presumably with emergent sporangia).

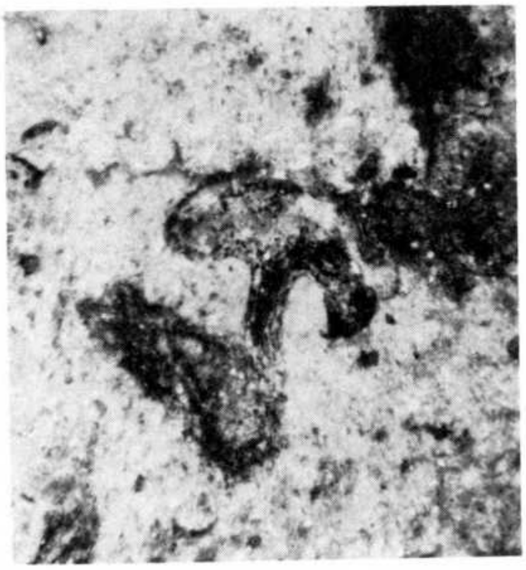

Fig. 3 Reniform terminal sporangium (×25).

Thus practising the caution advised by Banks[7], we can only conclude that the Irish flora certainly contains the earliest known erect fertile land plants and perhaps the earliest fertile vascular plants.

That they are the earliest *Cooksonia*-type sporangia is substantiated by faunal evidence. The necessity for accurate independent stratigraphical dating for any hypotheses relating to the phylogeny of vascular plants, in particular their ancestry and early evolution, has been emphasized elsewhere[1].

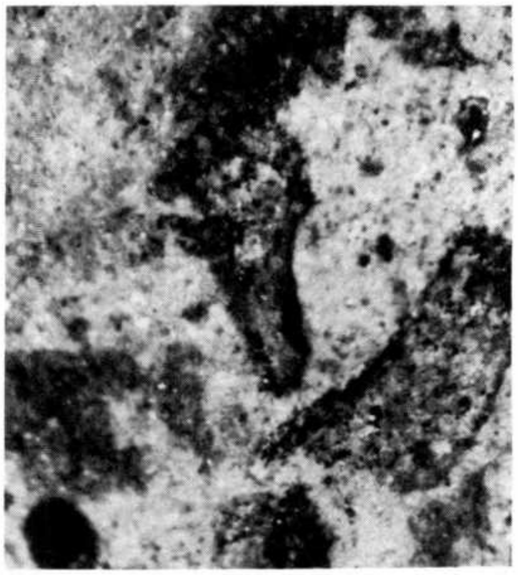

Fig. 4 Globose terminal sporangium (×23).

The rocks of the Devilsbit Mountain area constitute the northeastern end of an extensive inlier of Silurian rocks that extends south-westwards to include Silvermines and Slieve Phelim. The successsion, the overall thickness of which is probably in excess of 2,500 m, comprises a monotonous succession of turbiditic sandstones, laminated siltstones and mudstones, with very rare microconglomerates and volcanic rocks. The siltstones are frequently fossiliferous, yielding a varied fauna of *Cyrtograptus ludgreni* Zone age over much of the inlier[8–11]. To the south-east of Moneygall, near the northeastern end of the inlier, a small area of rocks of *Monograptus ludensis* Zone age is preserved in the core of a syncline in the vicinity of Cloncannon townland. These rocks are characterized by a fauna that includes *M. ludensis* Murchison, which is much the most abundant species present, and *M. auctus* Rickards together with nautiloids, phyllocarids, a small crinoid, occasional small brachiopods and epifaunal bivalves. The plant-bearing lithologies occur near the top of Borrisnoe Mountain, 1.7 km south-east of Moneygall (Grid reference 18 S 052782), near the southeastern edge of the Cloncannon syncline, and towards the base of the *ludensis* sequence, which attains a thickness of around 900 m. The age of the rocks in which the sporangia occur is confirmed by the presence of the two diagnostic graptolite species (identified by Dr R. B. Rickards) both above and below the plant fossils at the locality. Hence these Irish macroplants predate the lower *Baragwanathia* flora of Victoria, Australia even if the early Ludlow age is confirmed[12].

Perceptual learning specific for orientation and spatial frequency

Adriana Fiorentini & Nicoletta Berardi

Istituto di Neurofisiologia del Consiglio Nazionale delle Ricerche, Pisa, Italy

Several examples of 'perceptual learning' (improvement of some perceptual task with practice) have been reported$^{1-4}$. These studies are of great interest for neurological research because they demonstrate plasticity of the nervous system. Even for apparently basic perceptual tasks, such as visual acuity or vernier acuity^{1,4}, practice can facilitate a neural change which enhances performance. One question in this field is where does this learning occur? Indications about the possible neural site of a learning process may be derived from its specificity for some particular stimulus parameters. For instance, there is a hint that learning in global stereopsis may occur at a stage where visual information is processed by mechanisms selectively sensitive to different stimulus orientations^{3}. We report here an experiment on perceptual learning in the discrimination of gratings of different waveform. Our findings show that learning is specific for both the orientation and the spatial frequency of the practice stimulus.

The aim of the experiment was to evaluate the effects of training on the ability to discriminate gratings of different luminance distributions, to determine whether these effects were retained over time and to ascertain whether the effects would transfer to gratings of different orientations or different spatial frequencies.

The patterns to be discriminated (Fig. 1) were two complex gratings consisting of the sum of two sinusoids of spatial frequency f and $3f$, and contrast 40 and 13%, respectively ($\geqslant 1$ log unit above threshold). The two gratings differed only in the relative spatial phase of the two components. In grating *a* the two sinusoidal components had spatial phase 0°, like the first and third harmonic of a square wave. In grating *b* the spatial phase of the third harmonic was shifted by 90°. The luminance profiles of the two gratings are shown in the inset of Fig. 2.

The gratings were generated on a circular oscilloscope screen (Tektronix 503, 12-cm diameter) by a PDP11/10 computer at the rate of 2 ms per frame and viewed binocularly, with natural pupils. A black fixation dot of 3 mm diameter was superimposed at the centre of the screen. The average luminance of the screen ($10\ \mathrm{cd\ m^{-2}}$) was kept constant during and between grating presentations.

Discrimination of pairs of gratings of the same orientation, contrast and spatial frequency and with the luminance profiles shown in Fig. 2 was assessed with a two-alternative temporal forced-choice procedure. The gratings were presented successively for 16 ms (8 frames) each, with an interval of 500 ms. The order of presentation was varied quasi-randomly from trial to trial. Subjects reported after each trial in which of the two time intervals (indicated by a sound) grating *a* had been presented, and were informed whether their response was correct.

Two experienced and four naive subjects participated in the experiments. All subjects took part in three experimental sessions. In the initial 50–70 trials of each session, the gratings to be discriminated were vertical and viewed from 1.2 m, so that their fundamental spatial frequency was 1 cycle per deg. In the subsequent 80 trials, the gratings were either viewed from the same distance, but orientated horizontally (first experimental session), or orientated vertically and viewed from 60 cm (fundamental spatial frequency 0.5 c/deg, second session) or from 2.4 m (fundamental spatial frequency 2 c/deg, third session).

To evaluate changes in discrimination performance with training, the responses of each subject were grouped in subsequent blocks of 10 trials each. The corresponding blocks of trials of the six subjects were then pooled and the percentage of correct responses evaluated.

The results are presented in Fig. 2, where each point represents the average percentage of correct responses of the six subjects in successive blocks of 10 trials per subject (60 trials per point) relative to the three experimental sessions. The percentage of correct responses in the discrimination trials with vertical gratings of 1 c/deg (full points in Fig. 2) increased progressively during the first session from less than 70% in the first block of trials to more than 90% in the fourth to sixth block, and remained constant thereafter. The effects of trial repetition on discrimination performance with the same pair of gratings were almost completely retained in the second session, run on the next day (Fig. 2, middle left) and completely retained in the third session (Fig. 2, bottom left).

In contrast, the effects of training on discrimination performance with vertical gratings failed to transfer to horizontal gratings (Fig. 2, top right): the percentage of correct responses dropped to levels near chance when the gratings were presented horizontally, and a further 40–50 trials were required for performance to improve to a 90% level.

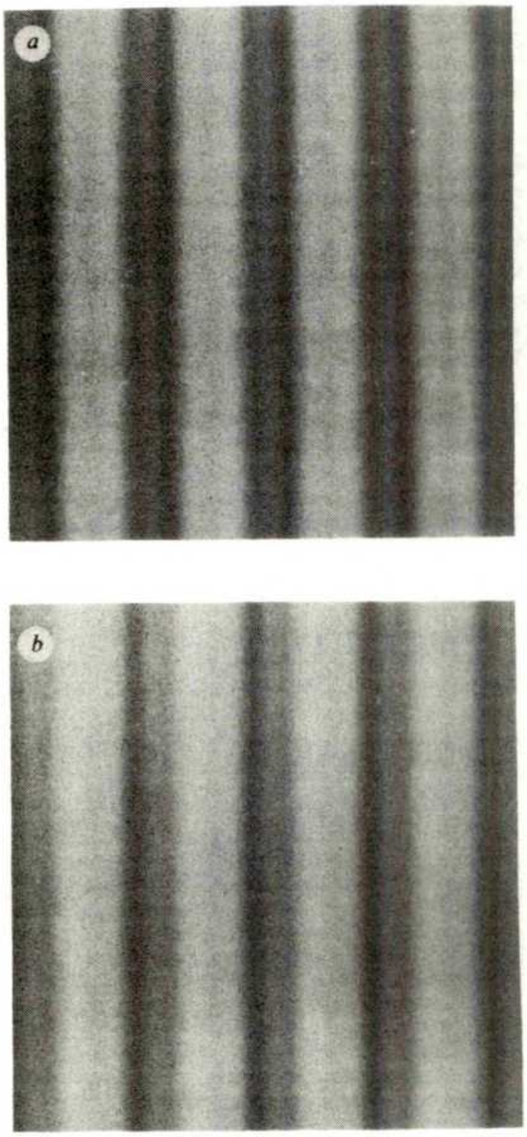

Fig. 1 Patterns to be discriminated: gratings *a* and *b*. The difference between the two patterns is obvious when they are viewed next to each other under steady illumination, but discrimination becomes more difficult when the patterns are presented briefly and in temporal sequence. The reader can appreciate this difficulty by illuminating the figure with a dim light flash.

0028–0836/80/360043—02$01.00

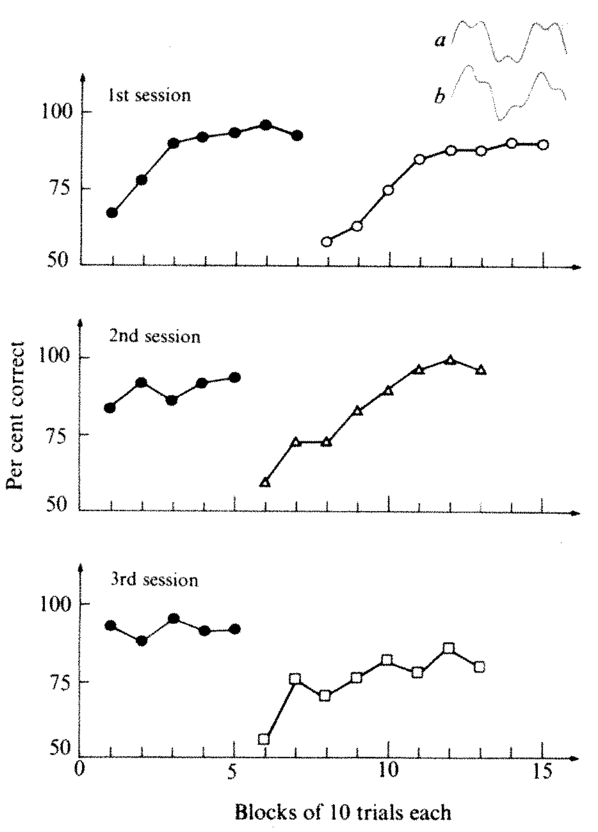

Fig. 2 Percentage of correct forced-choice discriminations of gratings *a* and *b* relative to subsequent blocks of 10 trials each. Data were pooled for the six subjects (60 trials per point). The three graphs refer to three experimental sessions run on separate days. Full points, vertical gratings, fundamental spatial frequency 1 c/deg; open points, horizontal gratings, 1 c/deg (top); open triangles, vertical gratings, 0.5 c/deg; open squares, vertical gratings, 2 c/deg. Insert, luminance profiles of gratings *a* and *b*. In the first session the proportion of correct responses with vertical gratings increased from 0.8 to 1.0 for some subjects and from 0.5 to 0.9 for others. The inter-subject variability was similar in the subsequent runs, whenever a new pair of gratings was used. The changes in the proportions of correct responses from the last block with the practice gratings to the first block with different gratings are all highly significant ($P<0.001$; two-tailed correlated t-test with six pairs of scores).

The same results were obtained in the following two sessions when the viewing distance was changed, so that the fundamental spatial frequency of the gratings varied from 1 to 0.5 c/deg (Fig. 2, middle right) or from 1 to 2 c/deg (Fig. 2, bottom right). In the latter case, performance levelled off at about 80% correct, probably because the third harmonic of the gratings was only slightly above threshold at this viewing distance.

In spite of the relatively small number of trials per point, the regular trend of the curves of Fig. 2 supplies unequivocal evidence that: (1) the ability to discriminate two complex gratings of different luminance profiles rapidly improves with training; (2) the effects of training on the discrimination of a given pair of gratings are retained, at least partially, from one day to the next; (3) the effects of training fail to transfer to gratings orientated at 90° or viewed from a distance differing by a factor of 2 (fundamental spatial frequency differing by 1 octave).

Experiments to be reported in detail elsewhere indicate that smaller changes in grating orientation (±30°) or spatial frequency (±0.5 octave) do not prevent the effects of previous practice from transferring to the new stimuli.

Most observers were able to describe the cues used for discrimination, once they had acquired practice in the task. According to their reports, the patterns were discriminated either on the basis of the apparent sharpness of the bar edges (the bars of grating *a* looking more similar to the black and white stripes of a square wave grating) or because of the detection of narrow dark and bright lines in grating *b* (corresponding to the points of lowest and highest luminance in the grating profile (Fig. 2). These cues, however, were apparently of little use when the orientation of the gratings or the viewing distance was changed. Furthermore, as measurements were made with a forced-choice procedure, the drop in performance cannot have resulted merely from a change in criterion. The improvement in performance with practice is therefore perceptual learning.

The neural mechanism for the learning process remains unknown. However, the present findings unequivocally show that this process must occur at a stage of neural processing at which different orientations (and/or different spatial frequencies) are handled separately.

We thank Professor L. Maffei and Dr D. C. Burr for critical comments on the manuscript. N.B. was supported by the Scuola Normale Superiore, Pisa.

T-cell specificity for H-2 and Ir gene phenotype correlates with the phenotype of thymic antigen-presenting cells

Dan L. Longo & Ronald H. Schwartz

Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland 20205

Experiments with chimaeric animals have demonstrated that the H-2 restriction specificity and immune response (Ir) gene phenotype of the T cell is acquired during development in the thymus. The mechanism by which this process occurs is unclear. One level of obligate expression of H-2 and Ir gene products is on the surface of antigen-presenting cells (APCs) which come from bone marrow precursors. We have now examined the turnover of APCs in the thymuses of F_1→parent (P) radiation-induced bone marrow chimaeras and found that APCs of donor phenotype appear at about 2 months after reconstitution. If the peripheral T-cell population is depleted after this time, new T cells emerging from the parental thymus (containing F_1 APCs) behaved like F_1 T cells, suggesting that cells from the bone marrow can influence thymic-directed T-cell differentiation. The thymic APC is an attractive candidate to play such a part in the development of the T-cell repertoire.

Experiments with (responder × nonresponder) $(R\times NR)F_1$ mice[1] and $NR\rightarrow(R\times NR)F_1$ chimaeric mice[2–8] have demonstrated that, for at least one major category of Ir genes, the APC must be of responder genotype to initiate Ir-controlled responses. In contrast, the T cell need not possess the responder allele(s) in its genome as long as it has developed in a responder environment[2–8]. Grafting of nonresponder animals with responder thymus tissue has shown that the thymus is responsible for the phenotypic alteration[9]. Anti-Ia antiserum blocking studies have shown that the genotypic nonresponder T cell becomes a phenotypic responder by learning to recognize Ia molecules of the responder type plus antigen on the surface of the APC[10]. The mechanism by which the chimaeric T-cell population acquires the ability to recognize responder Ia as self in the thymus is unclear, but seems to be a fundamentally different process from tolerance induction or depletion of specific alloreactivity[11]. It is presumed that the maturation of the

Table 1 Most thymic APCs in 1-year-old chimaeras are of bone marrow donor origin

Lymph node T cells from antigen-primed mice were collected by passage over nylon wool columns. Thymus cells which had been spun in a discontinuous BSA gradient and given 2,000R *in vitro* were used as sources of APCs. The APCs were pulsed with 60 μg purified protein derivative of *Mycobacterium tuberculosis* (PPD) or 100 μg poly-(Glu^{54}-Lys^{36}-Phe^{9})$_n$ (GLΦ) and 10^5 cells were added to 4×10^5 lymph node T cells in flat-bottomed microtitre plates. Antigen-specific proliferation was measured by assessing the ^{3}H-thymidine incorporated into DNA on day 5 of culture by antigen-pulsed versus non-pulsed APCs. The data are expressed as c.p.m. ± s.e.m. for triplicate cultures or as Δ, the difference between antigen-pulsed and non-pulsed cultures. B10.A thymus cells present PPD to B10.A and F_1T cells but not to B10.A(18R) T cells. F_1 thymus cells present PPD to all three types of T cells, and present GLΦ to the F_1T cells. The APCs from the thymus of B10 A→(B10 A×B10.A[18R])F_1 chimaeras present PPD well to B10.A and F_1T cells but poorly to B10.A(18R) T cells. This feature, along with the minimal amount of GLΦ-specific proliferation they induce in F_1 T cells, suggests that most of the APCs in the chimaeric thymus are of B10.A donor origin.

Table 2 Donor type APCs appear in the thymuses of F_1→P chimaeras about 2 months after reconstitution

B10.A animals were immunized with 10 μg DNP-ovalbumin (DNP-OVA) and (B10.A×B10)F_1 animals with the same dose of DNP-OVA and 30 μg GLΦ, all in complete Freund's adjuvant, in both hind footpads. Eight days later, lymph node T cells were obtained by passing lymph node cells over nylon wool columns 4×10^5 cells were plated with 2×10^5 antigen-pulsed or non-pulsed spleen cells or thymus APCs and antigen-specific proliferation was measured by subtracting the ^{3}H-thymidine c.p.m on day 5 of culture of non-pulsed spleen or thymus cells from the counts obtained with antigen-pulsed spleen or thymus cells Pulsing of cells was accomplished by preincubating *in vitro* irradiated (2,000R) spleen or thymus cells (10^7) with 100 μg of GLΦ or 60 μg of DNP-OVA in 1 ml of RPMI 1640 + 10% fetal calf serum for 1 h at 37 °C and washing thoroughly to remove any soluble antigen. Thymic APCs were obtained by taking the cells at the top interface of a discontinuous BSA gradient consisting of 35, 29, 27 and 11% layers which had been spun at 25,000*g* for 30 min. The ability of thymic APCs from (B10.A×B10)F_1→B10.A chimaeras to present GLΦ to F_1 immune T cells was assessed at varying times after reconstitution. The data show that at about 2 months after reconstitution, cells from the thymus of such chimaeras are able to present GLΦ to F_1 immune T cells and elicit an MLR in B10.A T cells, suggesting the presence of donor phenotype F_1 APCs

T cell to self-recognition in the thymus involves the T cell 'seeing' Ia products on the surface of some cell in the thymus. There are two cell types which have been proposed to have this role, thymic epithelial cells[11,12] and thymic macrophages[13]. Some studies have shown Ia molecules on the surface of thymic epithelial cells; however, the cell source of these molecules has not been conclusively demonstrated[14]. Macrophages have been found in the thymus and such cells have been reported to affect *in vitro* T-cell maturation[13]. Recently, we have demonstrated the existence of APCs in the thymus by a functional assay. The ability of such thymic APCs to present antigen can be eliminated by treatment with anti-Ia antiserum plus complement (data not shown). Thus, thymic APCs bear Ia antigens on their surface. We felt that a parsimonious theory of H-2 restriction and Ir gene function might be proposed if APCs in the thymus could be shown to be involved in T-cell maturation. Studies on the APC in spleen[4], peritoneal cavity[4] and skin (Langerhans cells)[15,16] have shown that its precursors originate in bone marrow. Thus, the theories on the cell responsible for exposing the T cell to what is self can be distinguished because, in a radiation-induced bone marrow chimaera, the radioresistant thymic epithelium should be replaced in turnover processes by host genotype epithelial precursors, while old or dying APCs should be replaced by APCs of donor marrow origin, if thymic APCs are similar to APCs in other sites.

To see if thymic APCs are replaced by bone marrow precursors, we examined the phenotype of the thymic APCs in parent (P) low responder→F_1 responder chimaeras. Such chimaeras were made by reconstituting irradiated poly-(Glu^{55}-Lys^{36}-Phe^{9})$_n$ (GLΦ) responder (B10.A×B10.A[18R])F_1 mice with T-cell-depleted GLΦ low responder B10.A bone marrow. Thymic APCs were isolated from B10.A→(B.10.A×B10.A[18R])F_1 chimaeras 1 yr after they were created by fractionating the thymus cells on a discontinuous bovine serum albumin (BSA) gradient (see Table 2 legend)[13]. As shown in Table 1, APCs from such chimaeric thymuses presented GLΦ poorly to F_1 immune T cells but successfully initiated a secondary proliferative response to purified protein derivative of *Mycobacterium tuberculosis* (PPD) in both F_1 and B10.A T cells but not in B10.A(18R) T cells. Also, note the presence of a large mixed lymphocyte reaction (MLR) when B10.A(18R) T cells were used as responders, as well as the negligible MLR made by B10.A T cells in response to the thymic APCs of the B10.A→(B10.A×B10.A[18R])F_1 chimaeras. These data support the notion that donor phenotype B10.A APCs predominate in the thymus, thus suggesting that thymic APCs in

Table 3 T-cell restriction specificity in $F_1 \rightarrow P$ chimaeras is converted from host to donor phenotype by ATS and cortisone treatment

(7) B10.A 3 months after ATS + cortisone	6,711 ± 278	61,827 ± 3,159	5,682 ± 495	6,653 ± 491	16,922 ± 957
(8) B6A F_1 3 months after ATS + cortisone	4,249 ± 368	81,889 ± 10,218	69,814 ± 5,117	57,431 ± 3,272	14,827 ± 966

Eight months after irradiating parental B10.A (A) and B10 (B) mice with 900–950 R and reconstituting them with T-cell-depleted $(B10.A \times B10)F_1(A \times B)$ or B6A F_1 bone marrow, the $F_1 \rightarrow P$ chimaeras were immunized with 10 μg DNP-OVA, 30 μg GLΦ, 50 μg (T,G)-A-L lot MC6 and 100 μg pigeon cytochrome *c* (gift of Drs E. Margoliash and M. Ultee) in complete Freund's adjuvant in both hind footpads. Eight days later, draining popliteal and inguinal lymph node cells were passed over nylon wool columns and 4×10^5 cells were plated in flat-bottomed microtitre plates with soluble antigen (20 $\mu g\, ml^{-1}$ DNP-OVA, 100 $\mu g\, ml^{-1}$ GLΦ, (T,G)-A--L and pigeon cytochrome *c*). Responses were quantified by incorporation of ^3H-thymidine into DNA on day 5 of culture. Lines 1, 3 and 5 show responses of $(A \times B)\, F_1 \rightarrow B10.A$, $(A \times B)\, F_1 \rightarrow B10$ and B6A $F_1 \rightarrow B10.A$ chimaeras, respectively. F_1 T cells are capable of making responses to all of the antigens tested, but when they develop in a parental environment they are restricted to responses characteristic of that parent. (B10 is a responder to DNP-OVA and (T,G)-A--L and a nonresponder to GLΦ and cytochrome *c*; B10.A is a responder to DNP-OVA and cytochrome *c* and a nonresponder to GLΦ and (T,G)-A--L). However, when cage partners of host restricted $F_1 \rightarrow P$ chimaeras were treated with 0.6 ml of a 1 : 10 dilution of ATS and 5 mg of cortisone acetate, both intraperitoneally, 3 months later their lymph node T cells behave like F_1 cells, that is they are responders to GLΦ, (T,G)-A--L and cytochrome *c* (lines 2, 4 and 6). Lines 7 and 8 show that ATS and cortisone treatment does not alter the phenotype of normal parental or F_1 T cells.

radiation-induced bone marrow chimaeras are ultimately replaced by bone marrow precursors.

The turnover of APCs in the skin and spleen after radiation is markedly different. Splenic APCs disappear within 3–4 days after irradiation and are totally replaced by bone marrow precursors about 7 days after irradiation[4]. Skin APCs, on the other hand, take 65–80 days to be replaced by bone marrow precursors[15,16]. In an effort to determine when thymic APCs in the radiation-induced bone marrow chimaera begin to be replaced by cells of donor origin, we made $(B10.A \times B10)F_1 \rightarrow B10.A$ chimaeras and assayed the antigen presentation function of their thymic APCs at varying times after reconstitution. As shown in Table 2, between 1 week and 1 month after reconstitution, $F_1 \rightarrow P$ thymic APCs were unable to present GLΦ to F_1 immune T cells and no significant MLR was elicited from parental type B10.A T cells. The ability of thymic APCs to present GLΦ to F_1 immune T cells first appeared 2 months after reconstitution, at the same time that a substantial MLR in B10.A T cells was seen. These findings suggested that, at 2 months after reconstitution, donor F_1 APCs were detectable in the thymus of $F_1 \rightarrow P$ chimaeras.

If thymic APCs are important in the development of the T-cell restriction repertoire, then the T cells emerging from a chimaeric thymus after its APCs have become donor genotype should have the donor's restriction specificity. However, T cells, even in 1-year-old chimaeras, behave as though they are restricted to host and not donor phenotype. One possible explanation for this is that the initial T cells maturing in the thymus of a radiation chimaera dominate the peripheral T-cell pool for most of the remainder of the animal's life. If so, new T cells maturing after turnover of APCs in the thymus would make a negligible contribution to the T-cell pool and thus no conversion of the responsiveness of chimaeric T cells would be seen. To test this, we took $F_1 \rightarrow P$ chimaeras 8 months after reconstitution at a time when their T cells were demonstrated to be restricted to cooperative interactions with cells bearing host (parental) major histocompatibility complex (MHC) products, treated them with anti-thymocyte serum (ATS) and cortisone to deplete them of peripheral and thymic T cells, and allowed their parental thymus containing F_1 APCs (Table 2) to repopulate the periphery with T cells. Three months after ATS and cortisone treatment, and 11 months after reconstitution, the mice were immunized and their lymph node T cells assayed. As shown in Table 3, $(B10.A \times B10)F_1 \rightarrow B10.A$, $(B10.A \times B10)F_1 \rightarrow B10$, and B6A $F_1 \rightarrow B10.A$ chimaeric T cells lost their restrictions to host genotype interactions and made substantial proliferative responses to GLΦ, (T, G)-A--L and pigeon cytochrome *c* (lines 1–6). They behaved like F_1 T cells. In control experiments, treatment of normal B10.A or B6A F_1 mice with ATS and cortisone had no effect on the Ir gene phenotype of their T cells 3 months later (lines 7, 8).

The most straightforward interpretation of these data is that self-H-2 is learned in the thymus by T cells upon interaction with MHC products on thymic APCs. The first T cells generated in an $F_1 \rightarrow P$ chimaera encounter parental APCs during maturation and become restricted to parental H-2 specificities. Those T cells emerging from a parental thymus, which has become repopulated with donor F_1 APCs, become restricted to F_1 H-2 specificities. This correlation between the phenotype of the thymic APC and the T-cell restriction repertoire suggests that thymic APCs may be involved in the development of T-cell self-specificity. Alternatively, it is possible that the results demonstrate that in $F_1 \rightarrow P_A$ chimaeras, a suppression mechanism exists[17] which prohibits detection of P_B and F_1-reactive T cells and which is sensitive to ATS and cortisone treatment. Once this suppression mechanism is blocked, P_B and F_1-reactive T cells can be expanded and detected. Our own preliminary experiments have failed to document any suppression of F_1 T-cell function in $F_1 \rightarrow P$ chimaeras. Therefore, we favour the former hypothesis.

The process by which the genome and the developmental milieu interact to produce the exquisitely precise T-cell recognition structure(s) which possesses dual specificities for antigen and MHC products remains an enigma. Evidence has been presented here that suggests that MHC products expressed on the APC in the thymus encountered by the T-cell precursor at a critical stage in its development may be responsible for its subsequent restricted cell interactions.

Cloned lines of natural killer cells

Gunther Dennert

Department of Cancer Biology, The Salk Institute for Biological Studies, PO Box 85800, San Diego, California 92138

A class of cytotoxic effector cells has recently been discovered[1,2] in normal and immunodeficient nude mice that lyse a wide range of targets of both tumour and non-tumour origin. Unlike other lymphocytes, these natural killer (NK) cells are present at high levels without prior priming and have no immunological memory. Because NK cells act without prior sensitization, they could have a crucial role in immunosurveillance, providing a first defence against arising neoplastic cells. The question of NK-cell specificity is not well understood; results so far suggest that they may recognize specific antigens on their targets. Thus unlabelled competitor cells can inhibit the cytotoxic reaction of NK cells[3]. Furthermore, target–effector binding can be inhibited by isolated target structures[4]. Experiments in which the lysis of mouse and human NK-sensitive targets was competitively inhibited with target suggested that the targets recognized by NK cells are not common ones. To study this important aspect, permanent lines and clones of NK cells have been established *in vitro*. I report here a successful attempt to do this, and show that sublines display the same specificity spectrum as NK cells from normal cells even after recloning. This proves that antigen receptors on NK cells are not clonally distributed but leaves open the two possibilities that NK cells either recognize common structures on NK-sensitive targets or carry many receptors each with a different specificity. Cell-surface markers of NK lines distinguished them from allospecific thymus-derived lymphocyte cell lines through their lack of Lyt-1 and Lyt-2 antigen.

Athymic mice are known to be deficient in functional T cells, yet do not experience a particularly high incidence of tumours. This observation has been attributed to the high NK activity of lymphoid cells from nude mice. These properties made spleen cells from nude mice an appropriate starting material to establish NK cell lines. A number of different supernatants conditioned by spleen cells stimulated with mitogens were tested as tissue culture media. Results showed that media derived from normal spleen cells stimulated with 10 μg ml^{-1} concanavalin A (Con A)[5] were superior to all others tested (data not shown) and supported the survival of effector cells from BALB/c *nu/nu* spleens able to lyse YAC-1 targets (Table 1, expt 1 and ref. 6). Fourteen individual spleen cell cultures were set up in conditioned medium, 12 of which were from BALB/c *nu/nu* mice and 2 from normal BALB/c mice. The cultures were fed weekly by replacing the medium and checked for cell growth. Twelve of the cultures grew progressively and were assayed after 4 months for their cytotoxic activity on YAC-1. Most cultures showed high cytolytic activity in a 6-h assay at attacker-to-target ratios (*a/t*) between 1:1 and 30:1 (Table 1, expt 2).

In subsequent experiments, all cultures were assayed on a panel of target cells, comprising YAC-1 and its relatively NK-resistant derivative, YAC-8 (provided by Drs M. Hansson and R. Kiessling), B10 ME and its relatively NK-resistant parent, BCN (provided by Drs P. Patek, J. Collins and M. Cohn), the C58 lymphoma RIGl and various spleen blast cells induced by bacterial lipopolysaccharide (LPS). There was no detectable difference between the various cultures, culture 11 being a representative example (Table 1, expt 3). There was no lysis on the H-2^k thymic lymphoma RIGl or in LPS spleen blast cells, which are excellent targets for cytotoxic T cells[7]. Strong lysis on YAC-1 and significantly lower lysis on YAC-8 were seen. Similarly to the YAC-1, YAC-8 pair, there was higher lysis on B10 ME than on BCN. Further experiments showed that lysis is independent of Con A because the assays could be performed in the presence of α-methyl mannoside (data not shown). These results showed that these cultures display NK-like activity. Cloning of two of the lines was attempted after they had been in culture for about 4 months. Earlier cloning was not feasible since the cultures seemed to go through a crisis at about 2–3 months after culture initiation. I chose culture 11, derived from a BALB/c mouse and culture 12 derived from a BALB/c *nu/nu* mouse, because they showed somewhat better growth and viability than the others. Both cultures were conditioned to growth at low cell density by seeding 1,000 cells in 0.2 ml into microtitres wells.

Once the cells had grown up they were transferred into bottles and cloning was attempted at 100, 30, 10 and 3 cells per well. Unfortunately, line 12 grew poorly and did not clone below 100 cells per well. In contrast, line 11 showed much better cloning efficiency in that about 30% of the wells with 10 cells per well grew. Individual colonies were grown up and assayed for cytotoxicity on YAC-1 targets. From Table 1, expt 4, it is seen that the sublines have various degrees of cytolytic activity. For instance, subline 11·2 has only 10% cytotoxicity at an *a/t* ratio of 3:1 while sublines 11·5 and 11·13 have 78% and 75% cytotoxicity respectively. Four individual sublines were assayed on four different targets at different *a/t* ratios and compared

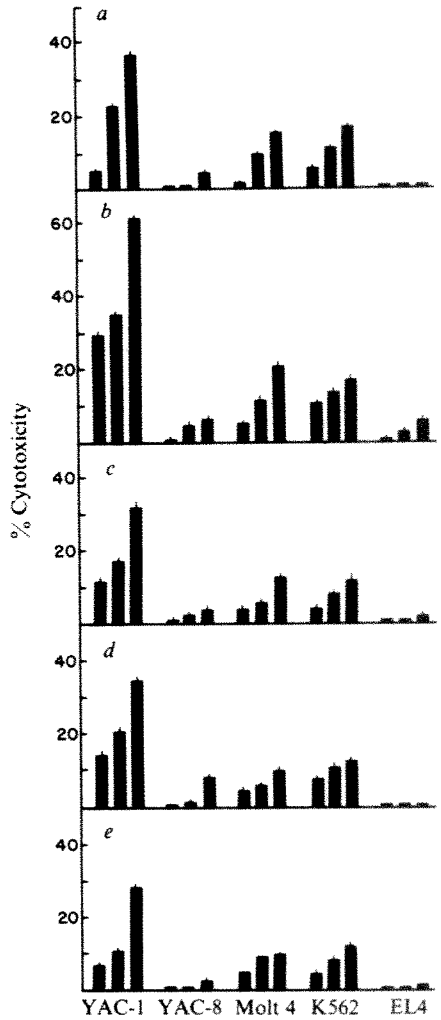

Fig. 1 BALB/c spleen cells (*a*) and the NK sublines 11·1 (*b*), 11·3 (*c*), 11·5 (*d*) and 11·11 (*e*) were assayed for their cytolytic activity on YAC-1 (H-2^a), YAC-8 (H-2^a), Molt 4, K562 and EL4 (H-2^b) targets. Molt 4 and K562 were grown in RPMI 1640 10% FCS and EL4 was grown in D-minimal essential medium plus 10% horse serum. *a/t* ratios were 25:1, 50:1, 100:1 for the spleen cells and 1:1, 2:1, 5:1 for the clones (from left to right). The 8 h time point is given.

Effector cells were assayed without prior culture or, spleen cells were cultured for 5 d in RPMI 1640 containing 5% fetal bovine serum (FCS), 5×10^{-5} M β-mercaptoethanol, 40% conditioned medium prepared from Con A stimulated spleen cells as described in ref. 5 for expt 1. For expt 2, cultures were fed with conditioned medium as above on a weekly basis for 4 months, then assayed on targets at one *a/t* ratio. For expt 3; after 4 months, culture 11 was assayed on YAC-1 (H-2^a), YAC-8 (H-2^a) B10ME (H-2^d), BCN (H-2^d), R1·G1 (H-2^k) and C57BL/6 and SJL blast cells induced by culture in bacterial lipopolysaccharide[11]. All target cell lines were grown in RPMI 1640 10% FCS except R1·G1 which was grown in Dulbecco's minimal essential medium plus 10% horse serum. For expt 4, culture 11 was cloned by limiting dilution in Falcon (no. 3040) microtitre wells in conditioned medium as in expt 1 at 1,000 cells per well, grown up and recloned at 10 cells per well. Individual colonies were grown up in Falcon tissue culture tubes (2051), then transferred to Falcon bottles (3013) and fed on a weekly basis. Cytotoxicity was assayed as described in ref. 11 at various *a/t* ratios as indicated. The time of incubation is given for each experiment. % Cytotoxicity = [(experimental ^{51}Cr release − spontaneous ^{51}Cr release)/(maximal ^{51}Cr release − spontaneous ^{51}Cr release)] × 100.

with the cytolytic activity of normal BALB/c spleen cells (Fig. 1). It is seen that BALB/c spleen cells lyse YAC-1 cells very well but YAC-8 and EL4 are not or are very poorly lysed. Both Molt 4 and K562 showed intermediate lysis. Sublines 11·1, 11·5 and 11·11 all showed the same picture comparable to that of BALB/c spleen cells: good lysis of YAC-1, poor lysis on YAC-8 and EL4, and intermediate lysis of Molt 4 and K562. Other sublines which were similarly tested showed the same lytic specificity.

This result could be interpreted in three ways: first, our sublines, if they were true clones, might recognize a common structure on mouse and human NK targets. This conclusion would contradict the previous results obtained with competitive inhibition assays mentioned above[3,4]. Second, NK effectors display more than one receptor each with different specificity on their cell surface. Consequently cloned effectors will lyse different targets using their respective specific receptors. Third, our sublines may not be true clones and consequently there may be different NK effectors with specific receptors in these sublines. Although cloning experiments cannot distinguish between the first two possibilities, the third possibility can be excluded by recloning. Sublines 11·3 and 11·8 were recently recloned at 1 cell per well. Assays on YAC-1, Molt 4, K562 and EL4 of five out of five clones from both sublines showed the same specificity as in Fig. 1 (data not shown). It is therefore likely that we are dealing with true clones. Hence, our NK sublines either recognize a common structure on these targets or display multiple receptors with different specificities. This finding does not exclude the possibility that there is another type of NK effector which expresses specific receptors clonally. In fact, Herberman *et al.*[8,9] recently presented evidence that the NK effectors may be heterogeneous in that both Thy 1^+ and Thy 1^- NK effectors exist. It was therefore interesting to assay our lines and sublines with regard to their cell-surface markers. The original line 11 as well as three sublines were assayed for Thy 1, Lyt 1, Lyt 2 and T200 using monoclonal antibodies and flow microfluorimetry. Table 2 shows that line 11 as well as the three

Table 2 Cell surface markers of NK cell lines

Effector cells	Thy 1	T200	Lyt 1	Lyt 2
Culture 11*	+	+	−	−
Subline 11·3*	+	+	−	−
Subline 11·10*	+	+	−	−
Subline 11·11*	+	+	−	−
C·C3·11·75†	+	+	+	−
BALB/c anti-C3H T killer cells‡	+	+	−	+

The following rat spleen cell–mouse myeloma hybrids producing monoclonal antibodies were used: T24/31.7 specific for Thy 1 (isolated by Dr I. S. Trowbridge); I3/2.3 specific for T200 (ref. 10); 53·7·313 specific for Lyt-1 and 53·6·72 specific for Lyt-2 both (provided by Dr L. Herzenberg).

* NK lines were assayed for cell-surface markers by flow microfluorimetry (FMF) using a rabbit anti-rat immunoglobulin as staining reagent.

† C·C3·11·75 is an allospecific H-2^d anti-H-2^k T cell line established in November 1975 from an MLR culture and maintained since then by allogeneic stimulation[11]. Assay by FMF as for the NK cell lines.

‡ BALB/c anti-C3H T killer cells were raised in a primary MLR and the effects of monoclonal antibodies assayed by complement dependent lysis.

sublines are Thy 1^+, T200$^+$ but Lyt 1^- 2^-. Since Ly 5 is a polymorphism of T200 glycoprotein[10], by inference these NK cells are Ly 5$^+$. The lack of Lyt 1 and Lyt 2 sets these cells clearly apart from allospecific lines of thymus-derived lymphocytes, which can be generated by a mixed lymphocyte reaction (MLR, ref. 11) and propagated by antigenic stimulation. Thus C·C3·11·75, a BALB/c (H-2^d) anti C3H (H-2^k) allospecific line[11], is clearly Lyt 1^+. In control experiments the same anti-Ly reagents were shown to be specific; thus anti-Lyt-1 in contrast to anti-Lyt-2 does not lyse allospecific T-killer cells. The expression of large amounts of Thy-1 antigen on these NK-cell lines, as well as the presence of these NK cells in thymus-deficient nude mice[6], may suggest that these cells do not require differentiation in the thymus for their function. Furthermore, since Thy-1 negative NK cells have been described[9], we may have to search for another class of NK cells, which may have different properties. Our cloned lines of NK cells may be instrumental in analysing the relationship of NK killing and antibody-dependent cell-mediated cytotoxicity. They also provide us with a powerful tool to unravel the nature of these cells and their significance in the immune surveillance against neoplasia.

We thank Susan Yamagata for technical assistance and Dr I. S. Trowbridge for performing the FMF analysis. This work was supported by NIH grants CA 15581 and CA 19334.

Involvement of the B-lymphoid system in chronic myelogenous leukaemia

Paul J. Martin*, Vesna Najfeld†, John A. Hansen*,

Studies with glucose-6-phosphate dehydrogenase (G6PD) isoenzymes have demonstrated that chronic myelogenous leukaemia (CML) is a clonal disorder of pluripotent haematopoietic stem cells which are capable of differentiation to myeloid cells, monocytes, erthrocytes and platelets[1]. It has been observed recently in G6PD heterozygous patients with chronic phase CML that the non-E-rosetting lymphocytes were restricted to a single enzyme type, indicating that some lymphoid cells must also arise from the leukaemic clone[2]. Surface or cytoplasmic immunoglobulin could be detected in up to 46% of the cells of these isolated non-T-lymphocyte populations, which suggested that cells from the CML clone were capable of differentiating into B lymphocytes. To investigate this further, we established Epstein–Barr virus (EBV)-transformed B-lymphoblastoid cell lines derived from patients with CML and studied chromosomes and G6PD to determine whether progenitor B lymphocytes for any of the cell lines had originated from the CML clone. We report here direct evidence that immunoglobulin-synthesizing B lymphocytes can arise from the CML stem cell clone.

Cells for this study were obtained from patient M.K., a woman with Philadelphia chromosome (Ph^1)-positive CML in the chronic phase and known to be heterozygous at the G6PD locus. Peripheral blood leukocytes (PBL) from M.K. were infected with EBV[3] and then dispensed into multiple wells of a microtray (0.5–1.0×10^6 cells per 0.2 ml). Cells from each transformed microculture well were expanded individually as separate cell lines. Preliminary results established that nearly all of the cell lines derived in this fashion from M.K. displayed either A or B G6PD. Furthermore, with some exceptions, a single class of cytoplasmic immunoglobulin heavy chain and light chain were identified in each line. Thus, at the time of study, nearly all of the cell lines were monoclonal. With conventional methods, it is not possible to determine simultaneously the immunoglobulin class, G6PD type and chromosomal composition of a single B cell. With these B-cell lines, however, it was possible to examine the progeny of a single cell for all three markers, and thus infer the phenotype of the progenitor cell for each of the lines.

In nine of the cell lines derived from M.K., 93% or more of the cells were Ph^1–positive (Table 1). In the cells of each of these lines, there was a translocation involving chromosome 7, as well as numbers 22 and 9, the two chromosomes usually involved in the Ph^1 rearrangement, giving the karyotype 46, XX, t(7; 9; 22) (q11 or 21; q34.0; q11.1) (Fig. 1). The same karyotypic rearrangement was present in the patient's unstimulated peripheral blood metaphases for at least 3.5 yr.

Only type B G6PD was detected in each Ph^1–positive cell line, identical to what was found in the blood cell leukaemic clone of this G6PD heterozygous patient[2]. In further studies, the differentiative capacity of the progenitors for four of the Ph^1–positive B-cell lines was examined by identifying the classes of immunoglobulin synthesized by each cell line. The data are presented in Table 1. In these lines, one-third or more of the cells were positive for cytoplasmic immunoglobulin. Moreover, the classes of immunoglobulin differed from line to line. Two cell lines were tested for the expression of Ia antigen and EBV nuclear antigen (EBNA), MK 12.4 and MK 24.6, and each line was positive for both markers.

For unexplained reasons it has not been possible to maintain these cell lines *in vitro* for long periods of time. All of the Ph^1-positive cell lines have lost viability after culture for 3 weeks to 5 months. Ph^1-negative B-lymphoblastoid lines derived from M.K. have been maintained in identical conditions without difficulty, and seem to have the same growth potential as B-lymphoblastoid cell lines derived from normal donors.

Ph^1-positive cell lines have been derived from at least two other CML patients[4,5]. One of these, NALM-1, is a pre-B-lymphoid cell line derived from the peripheral blood of a patient with CML in blast crisis. The other one, K562, was established from the pleural effusion of a patient with CML in blast crisis. K562 is capable of *in vitro* differentiation to haemoglobin-producing erythroid cells[6]. Both of these cell lines are EBNA negative, unlike the MK 12.4 and MK 25.6 cell lines described here.

We have used EBV to derive from a patient with CML a series of B-lymphoblastoid cell lines which originated from the leukaemic clone. A similar approach has been reported recently by Hurley *et al.* for the study of chronic lymphocytic leukaemia

(CLL)[7]. Anti-immunoglobulin idiotype reagents were used to demonstrate that some B-lymphoblastoid cell lines obtained from CLL patients had originated from the CLL clone. In cytogenetic studies, the cell lines which expressed the CLL idiotype were aneuploid, whereas lymphoblastoid cell lines which did not express the CLL idiotype were cytogenetically normal. Thus, EBV infection can transform some progeny of the malignant clone both in patients with CLL and in those with CML.

The finding of Ph^1 in B-lymphoblastoid cell lines derived from our patient directly demonstrates that precursor cells originating from the CML clone are capable of differentiating into immunoglobulin-producing B lymphocytes. Evidence supporting this conclusion has also been provided by the six reported cases of CML in blast crisis in which the majority of blasts were of the pre-B phenotype (cytoplasmic immunoglobulin positive, surface immunoclobulin negative)[8–10]. Although the immunoglobulin synthesis by these cells could reflect the differentiation potential of the original CML clone, the possibility cannot be excluded that immunoglobulin synthesis by a highly malignant (that is, blast phase) CML clone resulted from alterations in the genome that occurred as a secondary consequence of malignancy. Whatever the mechanism that resulted in immunoglobulin synthesis, the cells of these patients represented a monoclonal expansion of malignant blasts, as indicated by studies of the immunoglobulin light chain[8].

The cell lines described here provide evidence that cells of the malignant clone can differentiate into B lymphocytes even during the chronic phase of CML. These cell lines produce different classes of immunoglobulin, indicating further that this differentiation process is not limited to a single immunoglobulin species. This in turn suggests that immunoglobulin restriction is not fixed in stem cells of the CML clone, and that these cells may be responsive to the induction factors which normally regulate B-lymphoid differentiation. The diversity of differentiation seen for the CML clone during the chronic phase, demonstrated here by unrestricted immunoglobulin synthesis in Ph^1-positive stem cells, contrasts with the uniform immunoglobulin expressed by cells during blast crisis. Therefore, immunoglobulin restriction presumably occurs at some stage in differentiation between the pluripotent stem cell involved in the chronic phase of CML and the more differentiated blast cells present in the acute phase of the disease.

Table 1 Ph^1, cytoplasmic immunoglobulin and G6PD analyses of Ph^1–positive cell lines

Line	Ph^{1}* No. of Ph^1–positive cells / No. of cells studied	Cytoplasmic immunoglobulin (% of cells positive) μ	α	γ	κ	λ	G6PD
MK 3.10	70/70	31	0	0	0	33	B
MK 12.4	80/80	20	0	0	57	0	B
MK 12.7	95/95	0	17	0	0	75	B
MK 25.6	110/110	87	0	0	0	82	B

For chromosome studies, Ph^1 was enumerated in conventionally stained metaphases. After screening 30–50 mitoses, an additional 20–60 G–banded metaphases were analysed. More than 93% of cells from each of the B–lymphoblastoid cell lines were 46,XX,t(7;9;22)(q11 or 21:q34.0;q11.1) (see Fig. 1). Cytoplasmic immunoglobulin was stained as described with rhodamine–conjugated F(ab')$_2$ fragments specific for μ, γ, α, κ and λ (ref. 14). These reagents were provided by Dr S. M. Fu. Cells were examined with a Leitz Ortholux Two microscope with a 200 W mercury lamp and Ploemopak two filter system. A minimum of 300 cells were counted. For G6PD determination, cell lysates made by freezing and thawing were subjected to starch gel electrophoresis and the relative activity of the isoenzyme bands was estimated visually. The sensitivity of this technique enables a minor enzyme activity component of 5% to be detected[15].

* The data for the five other Ph^1-positive lines in which immunoglobulin was not studied are 60/60 for line MK-229.1, 78/80 for 12.15, 79/80 for 12.19, 28/30 for 31.2 and 30/30 for 12.23.

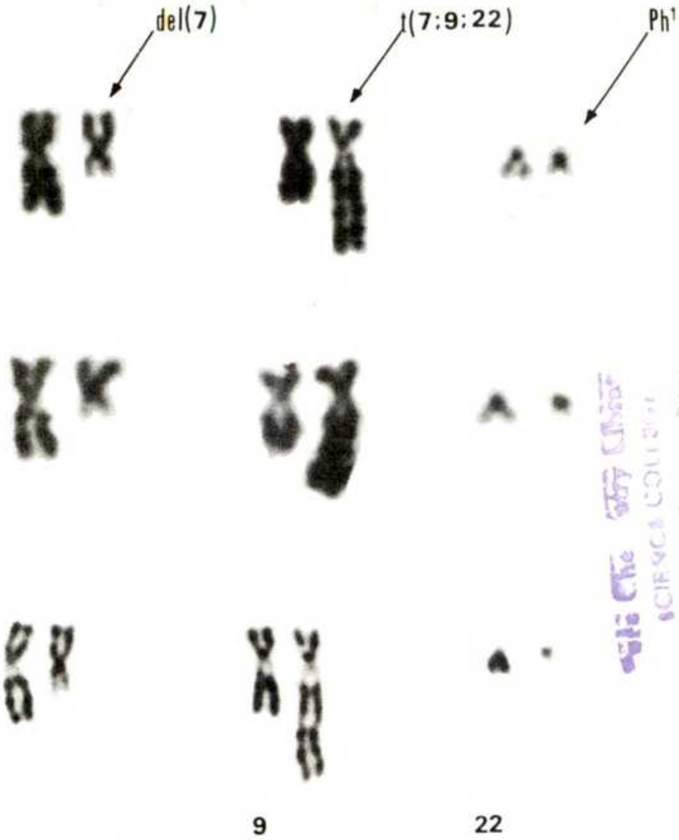

Fig. 1 Partial banded karyotypes of Philadelphia chromosome-positive B-lymphoblastoid cell lines. Colchicine (1 μg ml^{-1}) was added to the cell lines for the final three hours of culture, prior to fixation and staining. Slides were then subjected to a modified 'ASG' banding technique to obtain the banded karyotype of the cells[11]. Paris Conference[12] and its supplement[13] were used for chromosome nomenclature.

The Ph^1-positive B-lymphoblastoid cell lines derived from patient M.K., taken together with previous studies of this and similar patients[1,2], demonstrate that there exists in man a haematopoietic stem cell capable of B-lymphoid, as well as granulocytic, erythrocytic and megakaryocytic differentiation, and that this pluripotent stem cell is involved in CML.

Enzymatic assembly of slow reacting substance

B. A. Jakschik & L. H. Lee

Department of Pharmacology, Washington University Medical School,
St Louis, Missouri 63110

When basophils or mast cells are stimulated by a specific antigen they release chemical mediators, including a potent bronchoconstrictor, slow reacting substance of anaphylaxis (SRS-A). The structure of SRS from a mouse mastocytoma[1,2] and rat basophilic leukaemia (RBL-1) cells[3] has been identified as a thioether of arachidonic acid and glutathione[2,3] [not a thioether of cysteine as was originally thought[1]]. SRS has been named leukotriene (LT) C and may be formed by a novel lipoxygenase pathway which also synthesizes 5,6-oxido-7,9,11,14-icosatetraenoic acid (LTA) and 5,12-dihydroxy-6,8,10,14-icosatetraenoic acid (LTB)[1,4]. Homogenates of RBL-1 cells, when incubated with ^{14}C-arachidonic acid, form 5-hydroxy-icosatetraenoic acid (5-HETE) and 5,12-dihydroxy- and 5,6-dihydroxy-icosatetraenoic acid[5]. The latter is the spontaneous breakdown product of the labile intermediate LTA[4]. Formation of both compounds is stimulated by calcium. We have now produced biologically active SRS in a cell-free system generated from RBL-1 cells. Glutathione was essential for SRS synthesis and calcium stimulated its formation.

The experiments were carried out with 10,000*g* supernatant of RBL-1 homogenates[5,6]. The buffer used for the preparation contained 50 mM phosphate *p*H7, 1 mM EDTA, 0.1% gelatin and 14 μM indomethacin. Briefly, RBL-1 cells were washed once with buffer, resuspended at 5×10^7 cells per ml and homogenized on a Tekmar Tissumizer. The homogenate was centrifuged at 10,000*g* for 20 min. The formation of hydroxyacids from ^{14}C-arachidonate was determined by TLC as described previously[5,6]. SRS synthesis was monitored on the isolated, superfused guinea pig ileum[7]. Figure 1 shows the results of a typical SRS experiment. Addition of glutathione proved to be essential for the formation of SRS activity. No such activity was produced when cysteine was substituted for glutathione. The SRS activity was readily blocked by its specific receptor antagonist FPL 55712 (Fig. 1, Table 1). These data confirm earlier reports[2,3] that glutathione and not cysteine is part of the SRS molecule. The incorporation of glutathione rather than cysteine as such into SRS also agrees with our earlier observation with ^{35}S-cysteine[8]. A higher percentage of label was incorporated into SRS when RBL-1 cells were grown for 16 h in the presence of this amino acid as compared to brief exposure (1 h). These experiments had already suggested that cysteine was first incorporated into another compound before utilization in SRS synthesis.

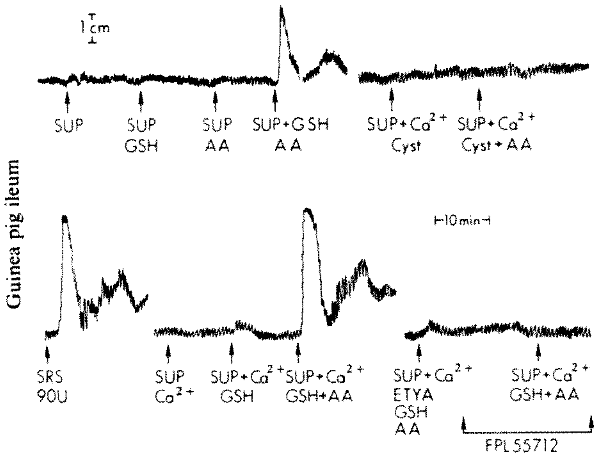

Fig. 1 SRS synthesis by a cell-free system. 10,000*g* supernatant of RBL-1 homogenates was incubated at 37 °C for 15 min with the agents indicated at the following concentrations: reduced glutathione (GSH) 1×10^{-3} M, calcium (Ca^{2+}) 2×10^{-3} M, cysteine (Cyst) 1×10^{-3} M, arachidonic acid (AA) 1.6×10^{-5} M, icosatetraynoic acid (ETYA) 6.7×10^{-5} M. 100 μl of the incubation mixture was tested on the superfused guinea pig ileum[7]. FPL 55712 was applied to the tissue at a concentration of 2×10^{-7} M. The SRS standard was generated from RBL-1 cells as described previously[9].

Table 1 Modulation of leukotrienes

	SRS Activity* (% max)	5,12-DHETE (% c.p.m.)†	5-HETE (% c.p.m.)†
Sup + Ca^{2+} + GSH + AA	100	6.1 ± 1.4	15.0 ± 7.0
Sup + GSH + AA	43.6 ± 8.7	–	–
Sup + Ca^{2+} + AA	0	25.9 ± 4.7	12.1 ± 1.5
Sup + AA	0	1.7 ± 0.5	2.3 ± 1.5
Boiled Sup + Ca^{2+} + GSH + AA	0	–	–
Boiled Sup + Ca^{2+} + AA	–	1.0 ± 0.4	1.2 ± 0.4
	% Inhibition		
ETYA‡	96.5 ± 3.5	90.6 ± 3.5	75.2 ± 2.9
FPL 55712	95.7 ± 2.2	–	–

* The 10, 000*g* supernatant (Sup) from RBL-1 cell homogenates was incubated and tested as in Fig. 1. The size of the contraction was evaluated by determining the area under the curve. The contraction obtained in the presence of Ca^{2+} 2×10^{-3} M, glutathione (GSH) 1×10^{-3} M and arachidonic acid (AA) 1.6×10^{-5} M, was arbitrarily taken as 100% ($n = 5$–7).

† The 10,000*g* supernatant from RBL-1 cell homogenates was incubated as described in Fig. 2 legend. Quantification was achieved by scraping and liquid scintillation counting ($n = 3$ or 4).

‡ Inhibition with icosatetraynoic acid (ETYA) or FPL 55712 was performed as indicated in Figs 2 and 1, respectively. The data are presented as mean ± s.e.m.

However, the addition of glutathione to the incubation mixture reduced the formation of 5,12-DiHETE (Fig. 2, Table 1). This observation suggests the preferential formation of SRS over 5,12-DiHETE. Therefore, the SRS-forming enzyme, probably a glutathione transferase, has a higher affinity for the proposed common intermediate, the 5,6-epoxide, than the enzyme synthesizing 5,12-DiHETE. The production of SRS in the presence of low concentrations of glutathione (Table 1) and lack of SRS formation when boiled supernatant was used, strongly indicate that this SRS formation is enzymatic. These data, therefore, confirm the postulate[1] that SRS is formed by the same enzymatic pathway as LTB with a common intermediate, LTA.

Similar to 5-HETE and 5, 12-DiHETE (Fig. 2, Table 1), SRS synthesis was stimulated by calcium (Fig. 1, Table 1). Therefore, calcium is important for this whole pathway. It is probably necessary for the first step since very little 5-HETE was formed in the absence of calcium (Fig. 2, Table 1). The enhancement of SRS formation by calcium does not appear to be quite as marked as for 5,12-DiHETE and 5-HETE. This may further indicate the preferential formation of SRS over 5,12-DiHETE. As can be seen in Table 1, there was a small, though not significant, increase in counts in the 5-HETE TLC area when no calcium was added to the incubation mixture as compared to incubations with boiled enzyme. Therefore, some hydroperoxide and LTA may be formed in the absence of exogenous calcium. The LTA is then preferentially converted to SRS. This would explain the formation of appreciable amounts of SRS in the absence of added calcium. Icosatetraynoic acid effectively inhibited the synthesis of all the products of the pathway (Figs 1, 2, Table 1).

0028-0836/80/360051—02$01.00

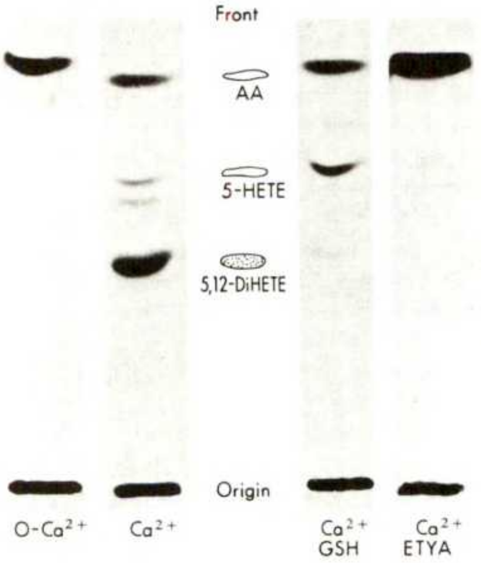

Fig. 2 Effect of glutathione and icosatetraynoic acid on 5,12-DiHETE formation. 10,000*g* supernatant (0.5 ml) was incubated with [1-^{14}C]arachidonic acid (AA) (200,000 c.p.m., specific activity 55 mCi mmol^{-1}) for 20 min at 37 °C, with the agents indicated: calcium (Ca^{2+}) 2×10^{-3} M, reduced glutathione (GSH) 1×10^{-3} M, icosatetraynoic acid (ETYA) 6.7×10^{-5} M. The reaction was stopped by precipitating the proteins with acetone. The *p*H was adjusted to 3.2–3.5 with 2 M formic acid. The mixture was extracted twice with 2 ml of chloroform. TLC was performed in solvent system A9, the organic phase of ethyl acetate/2,2,4-trimethylpentane/acetic acid/water (110:50:20:10; ref.[10]). Radioactive peaks were located by fluorography[11]. Standards were visualized by iodine staining. The identity of 5,12-DiHETE has been established by gas chromatography–mass spectrometry[5].

We are, therefore, now able to assemble SRS and the other LTs enzymatically in a cell-free system. The production of SRS by a cell-free system has not been reported previously despite many attempts. This preparation will enable us to study this pathway and its modulation in greater detail. The data presented here already indicate that in proper conditions SRS (LTC) is synthesized in preference to LTB. It will now be possible to investigate the requirements for each step in the pathway and determine what factors enhance or inhibit the formation of each product. The availability of the enzyme system in a cell-free preparation will allow the determination of substrate specificity for different fatty acids, glutathione analogues and sulphydryl compounds. Therefore, use of this enzyme preparation provides a tool for identifying LT synthesis inhibitors. The discovery of a specific SRS (LTC) inhibitor would be of special significance since SRS is such a potent bronchoconstrictor.

This work was supported by NIH grants 5-R01-HL21874-02 and 5-P30-CA16217-03. Prostaglandin standards were supplied by Dr J. Pike and 5-HETE by Dr R. C. Kelly (Upjohn), FPL 55712 by Fisons and icosatetraynoic acid by Roche.

Behavioural effects and supersensitivity following nigral dopamine receptor stimulation

Michael R. Kozlowski, Steven Sawyer & John F. Marshall

Department of Psychobiology, University of California, Irvine, California 92717

Nigrostriatal dopamine (DA)-containing neurones have the potential to modulate neostriatal output at two levels. First, DA released from the terminals of the DA-containing pars compacta neurones can act on striatal DA receptors. In addition, these pars compacta cells can release DA from their dendrites within the nigra[1–3]. Dendritically released DA could act at receptors located on these same cells ('autoreceptors')[4,5] or at receptors which are located on other nigral elements, especially strionigral afferent fibres[4,6,7]. However, although the stimulation of striatal DA receptors produces clear behavioural effects, no behavioural consequence of nigral DA receptor stimulation has been shown[8,9]. We report here that nigral DA receptor stimulation can produce clear behavioural effects in the appropriate circumstances. Unilateral intranigral injections of the DA receptor stimulant, apomorphine, produce clear contralateral turning in animals that (1) had been previously given intracerebral 6-hydroxydopamine (6-OHDA) injections, which extensively damage the ipsilateral nigral DA-containing cells, or (2) had been pretreated for 1 week with the DA receptor blocker, haloperidol. In addition, the turning produced by intranigral apomorphine in 6-OHDA-treated animals was much greater when the drug was given 14–17 days after the intracerebral neurotoxin than when it was given 4–7 days after, suggesting the development of supersensitivity to apomorphine in the nigra. These results suggest that the nigra must be considered as a site of action for drugs whose main effect is on the dopaminergic system.

Fifty male Sprague–Dawley rats (Simonsen Breeders) weighing 150–200 g had guide cannulae implanted 2 mm dorsal to the left substantia nigra. During the same surgery, 37 of these animals also received an injection of 6-OHDA (8 μg, Sigma) into the left ventral tegmental area (VTA) to destroy the mesotelencephalic DA-containing projection. Desmethylimipramine (15 mg per kg, intraperitoneally (i.p.)) was given 0.5 h before the 6-OHDA injection to protect brain noradrenaline-containing neurones. On days 4–17 postoperatively, all rats were given apomorphine injections through an inner cannula and were then placed in circular bowls where the number of complete rotations was counted for 1-min periods every 5 min for 1 h. After behavioural testing, the location of the cannula tracts was reconstructed from thionin-stained frontal sections of 20-μm thickness.

In agreement with the findings of others[8,9], injections of apomorphine (10 μg) into one substantia nigra of otherwise neurologically intact animals produced little behavioural effect. A small amount of contralateral turning was seen in two of the eight animals tested (Table 1). However, vigorous contralateral rotation occurred when intranigral apomorphine injections were given either 4–7 or 14–17 days after 6-OHDA injections into the ipsilateral VTA (Table 1). These 6-OHDA injections caused extensive ipsilateral DA depletion in both the forebrain (98, 80 and 82% decreases in the neostriatum, nucleus accumbens septi and olfactory tubercle, respectively) and the substantia nigra (90% decrease) when compared with the same structures in the opposite hemisphere. The turning produced by intranigral apomorphine in these DA-depleted animals was elicited in a dose-dependent manner (Fig. 1) and could be

0028-0836/80/360052—03$01.00

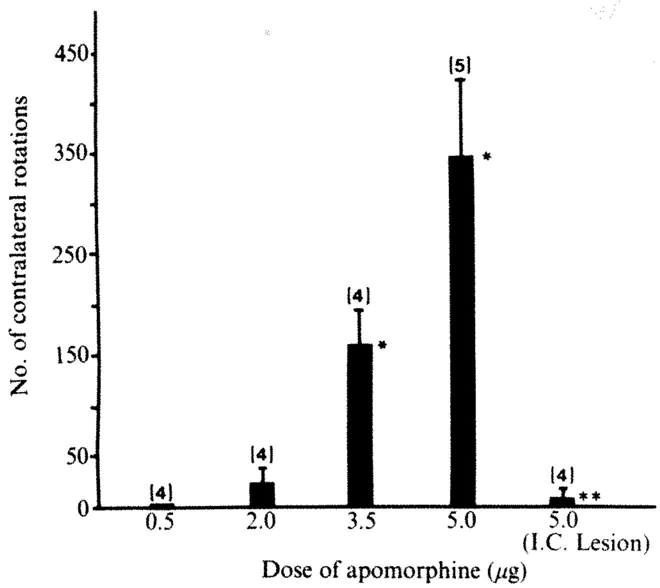

Fig. 1 Dose–response curve for contralateral rotation following intranigral apomorphine given 14–17 days after 6-OHDA treatment. The turning showed a significant dose dependence (*F*-test, $P<0.001$). Numbers in parentheses indicate animals per group. I.C. = internal capsule. 6-OHDA was dissolved in 0.9% saline and 0.1% ascorbic acid (2 μg μl^{-1}) and injected at a rate of 1 μl min^{-1} at the following coordinates: A 2.6, L 1.0, V 7.8. All rats were given desmethylimipramine (15 mg per kg, i.p.) 0.5 h before 6-OHDA. Guide cannulae were implanted at A 2.3, L 2.0, V 5.8–6.3. Apomorphine was dissolved in 0.9% saline and 0.1% ascorbic acid and injected into the substantia nigra in a volume of 0.5 μl at a rate of 1 μl min^{-1} through an inner cannula which extended 2 mm ventral to the tip of the guide shaft. The rats were placed in circular bowls for 1 h following the apomorphine injection, where their rotational behaviour was recorded. Radiofrequency lesions (100 V, 30 s) were made in the internal capsule using a stainless steel dental broach insulated except for 0.6 mm at the tip, positioned at A 4.0, L 2.6, V 8.3. In addition to receiving intranigral apomorphine, the 6-OHDA-treated rats were tested for rotation in response to a low dose (0.25 mg per kg, i.p.) of apomorphine as an index of extensive unilateral DA depletion. Those rats that did not show vigorous contralateral rotation (⩾200 turns) in the subsequent 1 h were not used in the experiment (~17% of the 6-OHDA-treated rats). The DA content (in μg per g wet tissue weight) of the striatum, nucleus accumbens septi, olfactory tubercle and substantia nigra in the right, non-injected hemisphere of 6-OHDA-treated rats were 6.7 ± 0.6, 6.5 ± 1.7, 4.3 ± 0.3 and 1.8 ± 0.5, respectively.
* Significantly more turning than 0.5 μg group, Dunnett's *t*-test, $P<0.05$; ** significantly less turning than 5.0 μg group, Student's *t*-test, $P<0.001$.

blocked by a single systemic injection of the DA antagonist, haloperidol (2 mg per kg, i.p., Table 1). The amount of rotation produced by 5 μg of apomorphine was much greater 14–17 than 4–7 days after the 6-OHDA treatment (Table 1).

Rotation in response to intranigral apomorphine was also seen in animals chronically treated with haloperidol (5 mg per kg, i.p., daily for 1 week followed by a 3-day drug-free period, Table 1). Such chronic haloperidol treatment produces behavioural supersensitivity to systemically administered apomorphine[10,11]. Interestingly, similar amounts of turning resulted from intranigral apomorphine injections iven either after 7 days of haloperidol treatment or 4–7 days after an intracerebral 6-OHDA injection (Table 1).

To investigate the possibility that the turning produced by intranigral apomorphine was mediated by DA receptors located on strionigral or pallidonigral axons, four animals were given small radiofrequency lesions along the course of these fibres in the medial tip of the internal capsule 11 days after an ipsilateral 6-OHDA injection into the VTA. These lesions nearly completely eliminated the rotation in response to intranigral apomorphine (5 μg, Fig. 1) 14 days after the 6-OHDA injection. They also reduced by 75% (*t*-test, $P<0.01$) the turning elicited by the systemic injection of apomorphine (0.25 mg per kg, i.p.). Histological sections showed that the radiofrequency lesions were centred in the medial tip of the internal capsule at a level of A 3.9–A 4.1 (ref. 12). These lesions extended an average distance of 1.0 mm in the antero-posterior plane, 0.6 mm in the medio-lateral plane and 1.2 mm in the dorso-ventral plane. In some brains, slight damage to the immediately adjacent zona incerta, ventral tegmentum and optic tract was found.

The effect of blocking receptors for γ-aminobutyric acid (GABA), a major transmitter in the strionigral and pallidonigral pathways[13,14], with the GABA antagonist, picrotoxin (0.5, 1.0 and 2.0 mg per kg, i.p.), was also examined. At 2.0 mg per kg, pictrotoxin completely blocked the rotation induced by intranigral apomorphine (5 μg, Table 1), but the two lower doses had no effect on turning (data not shown).

Histological examinations confirmed that the cannula tips for apomorphine injection were located in the pars reticulata of the substantia nigra. In a separate group of six 6-OHDA-treated animals in which the cannula tips were placed in the pars compacta, intranigral apomorphine injections produced little or no turning.

The substantia nigra contains at least two types of DA receptor. One type, located on the DA-containing cells of the pars compacta, binds the DA antagonist ^{3}H-spiroperidol with high affinity but does not seem to be linked to an adenylate cyclase[15]. The second type, located predominantly on nigral afferents (strionigral and possibly pallidonigral axons), is linked to adenylate cyclase but fails to bind ^{3}H-spiroperidol with high affinity[13,15]. Three findings indicate that the latter type is important in producing turning after intranigral apomorphine. First, the extensive depletion of forebrain and nigral DA produced by the VTA 6-OHDA injection suggests a massive degeneration of the dopaminergic cells, so that the rotation elicited by intranigral apomorphine is unlikely to be mediated by these neurones. Second, lesions of an area of the internal capsule through which strionigral fibres pass[16] almost completely eliminate this rotation. Third, systemic picrotoxin blocks this rotation, possibly by blocking GABA receptors postsynaptic to the strionigral fibres. However, because a high dose of picrotoxin was needed to block rotation (one-half the dose that is required to produce seizures), a non-physiological action of this drug cannot be ruled out.

Because DA can cause a release of GABA from nigral slices *in vitro*[17], we suggest that the apomorphine-induced turning behaviour is likely to result from a local stimulation of GABA release from strionigral axon terminals within the pars reticulata. This enhanced GABA release should then affect the

Table 1 Effects of 6-OHDA injections and pharmacological treatments on turning behaviour in response to intranigral apomorphine

Treatment	No. of animals	Apomorphine dose (μg)	No. of contralateral turns
1. Intranigral apomorphine only	8	10	1.4 ± 0.9
2. 6-OHDA injections 4–7 d before intranigral apomorphine	9	5	48.2 ± 14.0†
3. 6-OHDA injection 14–17 d before intranigral apomorphine*	5	5	344.6 ± 76.6‡

activity of nigral pars reticulata cells, which have been implicated in the production of rotational behaviour in other experiments[18,19].

In addition to these DA receptors located on pars compacta cells and on strionigral afferents, the nigra may contain additional DA binding sites, as combined lesions of nigrostriatal and strionigral projections do not totally eliminate nigral ^{3}H-spiroperidol binding[15]. An action of apomorphine at these sites may contribute to the behavioural consequences of its intranigral injection, particularly if they are located on nigral output cells. However, the present report offers no evidence for an action of intranigral apomorphine at these sites.

The effects of nigral DA receptor stimulation are strikingly similar to those caused by the stimulation of DA receptors in the neostriatum, a terminal field for the ascending dopaminergic axons. First, although unilateral injections of apomorphine into either the nigra or the striatum produce little behavioural effect in neurologically intact animals (ref. 20 and unpublished findings), injections into either region do produce vigorous contralateral turning following ipsilateral damage of the ascending dopaminergic system, a single injection of reserpine or chronic haloperidol treatment (ref. 20 and unpublished findings). Second, the rotation resulting from both striatal and nigral apomorphine injections seems to be mediated by strionigral fibres (ref. 21 and the present findings). These similarities suggest the intriguing possibility that the axon terminals and dendrites of the dopaminergic pars compacta cells provide a parallel, dual control mechanism for altering the activity of strionigral fibres and, consequently, for controlling the nigral output cells of the pars reticulata.

It is particularly interesting that robust turning in response to intranigral apomorphine occurs in the 6-OHDA- or chronic haloperidol-treated animals, but that only occasional rotations are seen in otherwise untreated animals given the intranigral apomorphine injection. This suggests that the nigra shows enhanced sensitivity to apomorphine following these treatments. The sharply increased rotational response to intranigral apomorphine found between 4–7 and 14–17 days after the 6-OHDA injection parallels the increased behavioural sensitivity to systemically administered apomorphine which develops during this period[22,23].

One process thought to underlie the development of enhanced sensitivity to DA agonists in the neostriatum following damage to the dopaminergic system is a proliferation of postsynaptic DA receptors, as indicated by an increased number of ^{3}H-haloperidol or ^{3}H-spiroperidol binding sites[24,25]. In the nigra, however, no increase in ^{3}H-spiroperidol binding occurs after destruction of the dopaminergic system[24]. This negative finding may reflect the fact that the high affinity ^{3}H-spiroperidol binding sites are largely localized to the DA-containing cells[15]. A possible increase in nigral DA-sensitive adenylate cyclase activity after this lesion has not been investigated. Alternatively, the increased sensitivity to apomorphine may result from changes in the receptors postsynaptic to the strionigral axons. Indeed, chronic treatment with haloperidol increases ^{3}H-GABA binding in the nigra[26,27].

These findings indicate that the nigra must be considered an important potential site of action of systemically administered drugs which act at DA synapses. Part of the contralateral rotation seen in unilateral 6-OHDA-treated rats given systeic apomorphine may be due to a direct nigral action of this drug. In addition, the nigra must be considered as a site of action of antipsychotic and anti-parkinsonian drugs. Finally, the development of an enhanced sensitivity to DA within the nigra may contribute to the behavioural recovery that occurs after subtotal damage to the ascending DA-containing fibres[28,29].

We acknowledge the gifts of haloperidol from McNeill Laboratories, desmethylimipramine from Merrill Laboratories and apomorphine from Dr R. J. Baldessarini. This research was supported by PHS grant MH 31426 and by NSF grant BNS-7914092 to J.F.M. M.R.K. was supported by PHS training grant MH 14599.

The role of microvesicles in buffering $[\mathrm{Ca}^{2+}]_i$ in the neurohypophysis

It is well established that hormone release from neurosecretory nerve terminals is triggered by an increase of the cytoplasmic ionized calcium concentration which occurs after the arrival of action potentials[1]. For the neurosecretory nerve terminals to recover their basal Ca^{2+} concentration, the calcium which has entered during depolarization must be extruded and/or accumulated in subcellular organelles or bound to some cytoplasmic proteins. Neurosecretory nerve endings are characterized by the presence of hormone-containing granules and microvesicles (earlier referred to as 'synaptoid' vesicles). The role of these microvesicles has been the subject of debate and has recently been reviewed[2]. One of the most attractive hypotheses has been that these organelles represent the retrieved membrane of the granule after exocytosis. However, on stimulation of hormone release, the number of microvesicles does not increase, suggesting that they do not participate in the endocytotic process[3]. Using stereology as a quantifying method, we recently demonstrated a redistribution of microvesicles towards the release site during potassium-stimulated hormone release[3]. It is thus possible that microvesicles in neurosecretory nerve terminals might function as calcium accumulating organelles as suggested for the coated vesicles isolated from the cerebral cortex[4,5]. We report here that a microvesicle-containing microsomal fraction isolated from neurosecretosomes (isolated neurosecretory nerve terminals) possesses an ATP-dependent calcium transporting system. This system enables the fraction to accumulate calcium ions when the external ionized calcium concentration is <1 μM, which is in the physiological range.

Bovine neural lobes (40–60 for each experiment) were collected from the local slaughterhouse and kept in ice-cold 0.3 M sucrose buffered with 10 mM HEPES, *p*H 7.2. The glands were carefully dissected out, minced with a pair of scissors and sliced on a MacIlwain tissue chopper at 0.5-mm intervals. The material was then homogenized at 800 r.p.m. in a Teflon homogenizer and the homogenate was centrifuged at $800g_{av}$ for 10 min on a RC-5B Sorvall centrifuge using an HB-4 type rotor. The procedure was repeated with the resulting pellet (P_1) after a further homogenization. The two supernatants were mixed and centrifuged at 1,700*g* for 20 min. The resulting pellet (P_2), which consisted mostly of neurosecretosomes[6], was homogenized in 0.3 M buffered sucrose and the homogenate centrifuged at $26{,}000g_{av}$ for 20 min. The supernatant from this was centrifuged at $100{,}000g_{av}$ for 1 h. The resulting pellet (P_4) was practically devoid of mitochondria and neurosecretory granules, as judged by careful analysis of ultra-thin sections. P_4 was resuspended in 0.15 M KCl, 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, *p*H 7.2, and its protein content determined using the method of Lowry *et al.*[7]. In one experiment P_4 was fixed by the method described by Shaw and Morris[8]. The pellet consisted primarily of microvesicles an many of them contained precipitate indicating the presence of calcium. Figure 1 shows the time course of calcium uptake by the microvesicle-containing fraction at two different calcium concentrations. This uptake is ATP-dependent and is abolished by addition of the ionophore X537A. The amount of calcium taken up by the microvesicles-containing fraction is higher than that found for a microsomal fraction isolated from pinched-off presynaptic nerve terminals from rat brain cortex[9]. Neither the time course nor the amount of calcium uptake was affected by addition of mitochondrial inhibitors such as ruthenium red (10 μM), antimycin (0.05 μg ml^{-1}) or carbonyl cyanide trifluomethoxyphenyl hydrazone FCCP (0.1 μg ml^{-1}). These results suggest that fragments of mitochondria are not responsible for the ATP-dependent calcium uptake of the microvesicle-containing fraction.

The effect on the Ca^{2+} uptake of the ionophore X537A (Fig. 1) is not due to the influence of an increased membrane permeability to Na^+ ions because (1) the microvesicles were incubated in a sodium-free medium, and (2) addition of sodium (20–40 mM) did not release calcium which had previously been accumulated. The lack of effect of sodium on the calcium accumulated by the microvesicle fraction shows that the preparation used in the present study is unlikely to be contaminated by plasma membranes because a Na^+–Ca^{2+} exchange has been demonstrated in neurohypophyses isolated *in vitro*. Furthermore, the efflux of calcium from preloaded glands does not increase on addition of veratridine, an alkaloid known to increase the sodium conductance in nervous tissue. It thus seems that in neurosecretory nerve endings the release of calcium from the microvesicles is not modulated by the cytoplasmic sodium concentration.

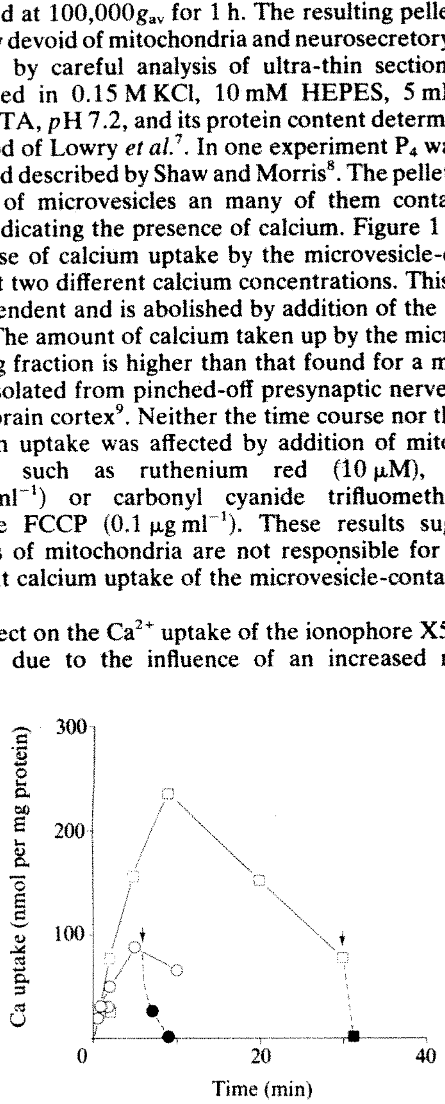

Fig. 1 ATP-dependent Ca^{2+} uptake in microvesicle-containing fraction isolated from bovine neurohypophysis. The preparation (200–300 μg protein ml^{-1}) was preincubated at 37 °C in 5 ml of a medium containing 150 mM KCl, 5 mM $MgCl_2$, 10 mM HEPES, *p*H 7.2, ^{45}Ca-EGTA buffer. After 5 min, 4 mM ATP (final concentration) was added. At different times, 500-μl aliquots were withdrawn and immediately filtered through Millipore filters (0.22 μm pore diameter) as described in ref. 15. 100 μl of the resulting filtrates were counted in a liquid scintillation spectrophotometer. The calcium transport studies were always performed immediately after the isolation of the microvesicle-containing fraction because calcium uptake by the preparation was much lower 16–18 h after the final centrifugation. In some cases, a calcium binding of 10–20 nmol per mg of microsomal proteins was observed in the presence of 4 mM ADP. The ionized calcium concentrations were 0.66 μM (○) and 0.91 μM (□). At the time indicated by the arrow the ionophore X537A (10 μM final concentration) was added (●, ■).

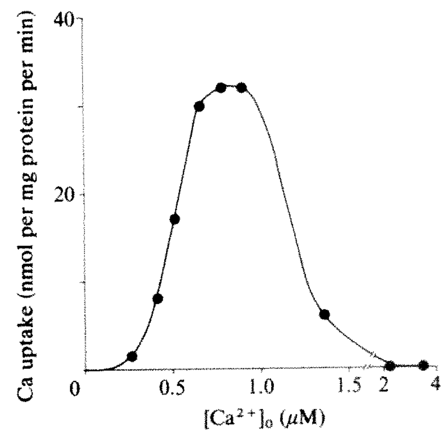

Fig. 2 Effect of free Ca^{2+} concentration on calcium uptake by the microvesicle-containing fraction. Experimental conditions as described in Fig. 1 legend. The calcium in the incubation medium was buffered to the indicated ionized Ca^{2+} concentration with EGTA (1 mM) by taking a Ca-EGTA stability constant of 1.86 × 10^{-7} M. The rate of calcium uptake was obtained from the initial slope of the kinetics illustrated in Fig. 1. The apparent K_m of the Ca^{2+} transport system lies between 0.4 and 0.6 μM. Curve drawn by eye.

The non-mitochondrial ATP-dependent Ca^{2+} transport system described above has a high affinity for calcium. After the calcium has been accumulated into the microvesicle-containing fraction, it can be released passively (Fig. 1). The rate of calcium release is a function of the amount of accumulated calcium. This release of calcium on overloading of the fraction has been observed in other systems[10]. In a series of experiments, aliquots of the microvesicle fraction were incubated in media containing different concentrations of ionized calcium. The rate and the amount of calcium taken up were measured as a function of $[Ca^{2+}]$ in the medium ($[Ca^{2+}]_o$) and the results are illustrated in Fig. 2. The apparent K_m^{Ca} for this transport system is 0.4–0.6 μM. These values lie within the apparent range of cytosolic Ca^{2+} ions, and are similar to those reported for a microsomal fraction isolated from lysed synaptosomes[9]. A pronounced inhibition of the Ca^{2+} transport activity is observed on increasing the free calcium concentration above 1 μM (Fig. 2). This phenomenon can be related to the competition between Ca^{2+} and Mg^{2+} for ATP utilization described in other systems[11].

The present study therefore provides a demonstration that, as suggested earlier[3,12], the microvesicles found in neurohypophysial nerve endings have the capacity to take up calcium and therefore may be involved in controlling the ionized cytoplasmic calcium concentration. The presence of calcium in some microvesicles has been demonstrated previously using the pyroantimonate technique[12]. More recently, Shaw and Morris have been able to demonstrate, using a combined oxalate–pyroantimonate method, the presence of calcium in microvesicles in fixed neural lobes[8]. Microsomal calcium uptake by neurosecretory tissue has previously been shown but the data do not provide information about the origin (nerve cells or pituicytes) of these microsomes[13]. The high affinity (Fig. 2) of the calcium transport system isolated from neurosecretosomes suggests that microvesicles may have an important role in intraterminal Ca^{2+} buffering. Although mitochondria take up calcium, their calcium transport system has a much higher K_m^{Ca} (ref. 14) than the microvesicle fraction. As the arrival of a burst of action potentials is likely to increase the intraterminal ionized calcium concentration from 10^{-7} to 5×10^{-6} M at the most, the microvesicles would buffer the $[Ca^{2+}]_i$ in this range. How the calcium accumulated in microvesicles is released from the nerve terminal is not known. Electron micrographs often show fusion of microvesicles with the plasmalemma and this suggests that the calcium could be released by exocytosis. Alternatively, calcium could be slowly released into the cytoplasm and long-term calcium homeostasis be controlled by some transport system located in the plasma membrane.

Neurosecretory nerve endings in the rat neurohypophysis release their hormones by exocytosis[1] subsequent to an influx of calcium from the external medium[2]. The nerve endings are characterized by the presence of neurosecretory granules, mitochondria, occasional vacuoles, and a population of microvesicles similar in appearance to spherical synaptic vesicles. The function of the microvesicles has, for a long time, been uncertain. In view of evidence that coated microvesicles isolated from cerebral cortex are capable of ATP-dependent calcium accumulation[3], a method has now been developed for the visualization of calcium in the neurohypophysis at the ultrastructural level. With this technique, calcium precipitates are consistently seen in the microvesicles, mitochondria and glial cell (pituicyte) nuclei. In addition, the pituicyte cytoplasm and perivascular space show a diffuse precipitate which can be removed by washing the tissue prior to fixation. The function of the microvesicles might therefore be to sequester calcium within the nerve endings.

The subcellular distribution of calcium in the rat neurohypophysis was studied by a modification of a technique previously described[4]. Adult male rats of the Porton–Wistar strain were anaesthetized with urethane and perfused with a glutaraldehyde fixative containing potassium oxalate, preceded in some cases by a wash with potassium phosphate buffer containing dextran. The posterior pituitaries were dissected out, washed in an oxalate solution, and treated with an osmium tetroxide fixative containing potassium antimonate. The tissue was then washed in distilled water, dehydrated, and embedded for electron microscopy. Control tissue was fixed in solutions lacking oxalate and antimonate. Immersion in osmium/(pyro)antimonate fixatives has been widely used to visualize calcium in nervous and glandular tissue, but it gives relatively poor preservation of fine structure especially in the central nervous system[5–7]. Initial fixation by perfusion with a rapidly penetrating aldehyde, as described here, allows much better preservation[6,7], at the same time immobilizing tissue calcium by precipitation with oxalate.

The neurohypophysis is largely composed of axons and terminals of magnocellular hypothalamic neurones, and of pituicytes. The unmyelinated neurosecretory axons are characterized by numerous dilatations containing neurosecretory granules and mitochondria; neurosecretory nerve endings in addition contain abundant microvesicles, and contact a basement membrane adjacent to a fenestrated capillary[8] (Fig. 1*a*). With the technique used, calcium is indicated by the electron-dense precipitate of antimony (Fig. 1*b–d*). When the neurohypophysis was perfused directly with the oxalate/glutaraldehyde fixative, a striking ultrastructural feature was the presence of abundant precipitates in the cytoplasm and nuclei of the pituicytes, to the extent that their processes were clearly outlined at low power (Fig. 1*b*). A dense precipitate was also present in the perivascular space, and more diffuse deposits were seen over the neurosecretory axons, swellings and terminals. The mitochondria of both neurones and glia were heavily stained; vacuoles usually contained precipitate and virtually every microvesicle contained a single, dense particle of precipitate.

This appearance was significantly altered if the tissue was washed with phosphate buffer solution containing dextran (which facilitates perfusion[9]) for 3–5 min before infusion of fixative. The perivascular space was thereby rendered completely free of precipitate and the diffuse precipitate over neurosecretory elements was also removed. However, precipitate remained localized within the microvesicles, whether they were dispersed (Fig. 1*c*) or in clusters (Fig. 1*d*) and in the vacuoles. Smooth endoplasmic reticulum elements also often contained the stain, and were occasionally seen in intimate association with the microvesicles (Fig. 1*d*). The mitochondria of both neurones and pituicytes (Fig. 1*c*, *d*) retained their precipitates, but the cytoplasmic precipitates in the pituicytes were removed and the precipitate in their nuclei considerably reduced in extent (Fig. 1*d*). Washing with buffer–dextran for 1–2 min produced an intermediate appearance, in which the perivascular space and pituicytes contained a precipitate which was less dense than when fixative was introduced immediately.

Various control experiments suggest that the precipitate visualized was due to calcium in the tissue. Inclusion of 5 mM EGTA in the oxalate wash before osmium/antimonate fixation resulted in the complete absence of deposits when the tissue was subsequently examined, and also demonstrated that they were not an artefact of the fixative procedure itself. Precipitate could also be removed from ultra-thin sections on grids by incubation in 5 mM EGTA at 60 °C for 1 h. This indicates that the deposits do not contain significant amounts of sodium or magnesium (which antimonate will precipitate at higher concentrations[10]).

The diffuse cytoplasmic precipitates seen in tissue exposed to glutaraldehyde/oxalate directly could conceivably be due to *in vivo* ambient levels of free calcium, though it would be difficult to explain their presence in greater amounts in the pituicytes. It seems more likely that they result from the influx of calcium ions from the extracellular space as the tissue dies[11]. However, glial cells can apparently store calcium[12], and pituicytes are capable of taking up radioactive calcium when stimulated with potassium[13]. The presence of gap junctions between pituicytes has led to the suggestion that they might modulate neurosecretory

0028–0836/80/360056—03$01.00

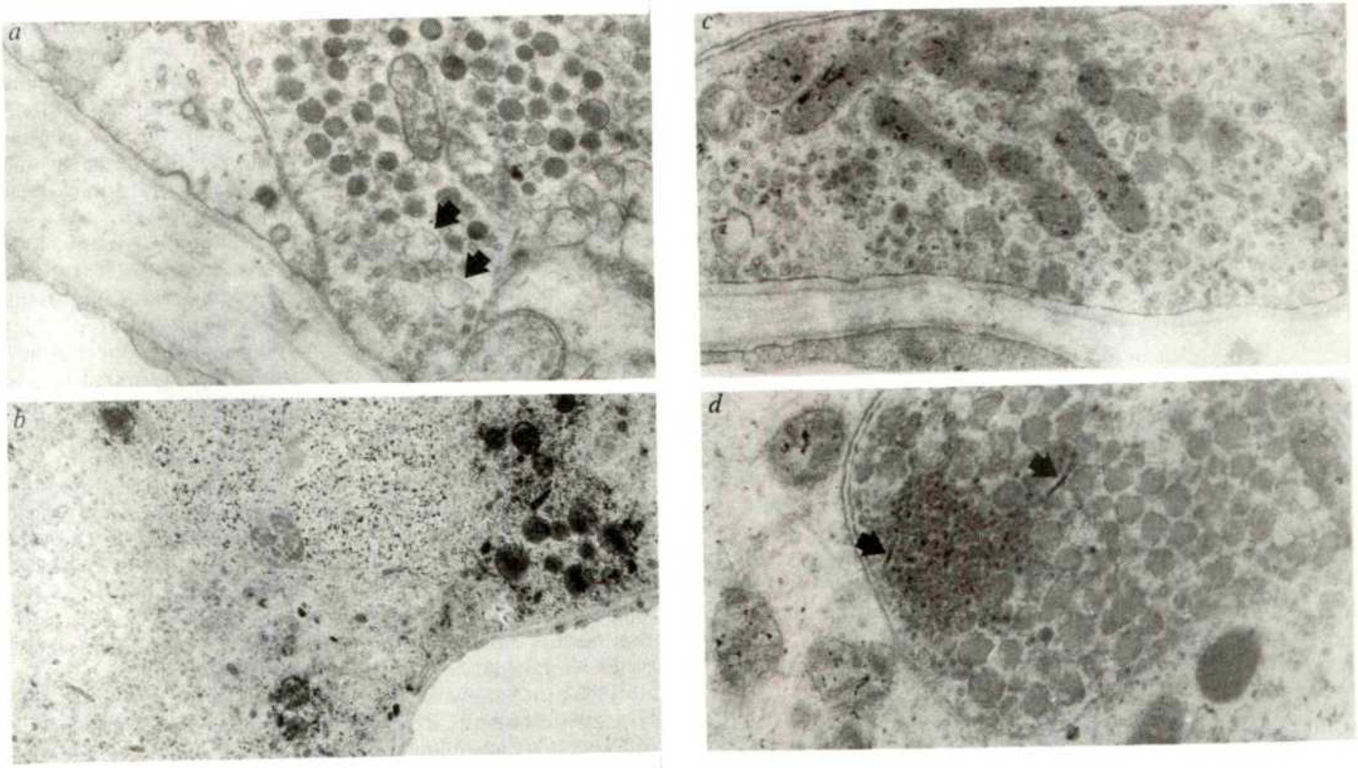

Fig. 1 Electron micrographs of control (*a*) and oxalate/antimonate treated (*b–d*) neurohypophyses. Animals were perfused through an aortic cannula for 10 min with 2.5% glutaraldehyde, 90 mM potassium oxalate, *p*H 7.2. In some cases, this was preceded by 150 mM potassium phosphate buffer and 3.4% dextran (molecular weight 40,000), *p*H 7.2, for 1–5 min. The neurohypophyses were dissected out after 16 h and washed for 30 min in 90 mM potassium oxalate, 7.5% sucrose, *p*H 7.5. The tissue was postfixed for 2 h in 1% osmium tetroxide, 2% potassium antimonate, washed in dilute potassium hydroxide, *p*H 10, for 15 min, dehydrated rapidly in a graded series of alcohol, and embedded in Spurr resin using propylene oxide. Control tissue was fixed in an identical fashion except that potassium chloride replaced oxalate in the prefix and wash, and 100 mM sodium cacodylate replaced antimonate in the postfix. *a*, Neurosecretory terminal, control method. The terminal lies in contact with a basement membrane, separated from a fenestrated capillary endothelium by a wide perivascular space. It contains neurosecretory granules, mitochondria, and microvesicles, some of which are clustered near the basement membrane contact zone; two vacuoles are also present (arrows; ×18,000). *b*, Low power view of tissue fixed directly with glutaraldehyde/oxalate. The nucleus and cytoplasm of a pituicyte (upper region of picture) contain much more precipitate than the surrounding neurosecretory elements; the pituicyte cytoplasm also contains characteristic lipid droplets (×2,700). *c*, Neurosecretory terminal in tissue washed before glutaraldehyde/oxalate fixation. Precipitate is highly localized to mitochondria, microvesicles (in a dispersed configuration here) and a vacuole; it is absent from the perivascular space (×25,000). *d*, Microvesicles in a clustered formation adjacent to a pituicyte in washed tissue. Precipitate is again localized to microvesicles and mitochondria, and also in smooth endoplasmic reticulum associated with the microvesicles (arrows). The pituicyte cytoplasm is almost completely free of precipitate (×25,000).

activity by ionic movements into and through their cytoplasm[14]. The observation of calcium precipitates above background level in the pituicyte cytoplasm could reflect such a function.

The diffuse cytoplasmic precipitate was rapidly washed out of the neural elements but the mitochondria, vacuoles, smooth endoplasmic reticulum and microvesicles appear to be sites of tightly bound calcium. Intracellular binding sites have been proposed to account for the return of the intracellular ionized calcium level to the very low resting value once stimulation has ceased[15]. Localization of calcium in mitochondria was entirely expected in view of their proven calcium-accumulating properties[16], but the available data suggest that the kinetics of brain mitochondrial calcium uptake are not appropriate for dealing with stimulus-induced increases in the level of ionized calcium in nerve terminals[17], when the concentration probably rises from about 10^{-7} to 10^{-5} M at most[18]. Mitochondria may well serve as long-term buffers of neuronal intracellular calcium, however[15]. Deposits in the vacuoles, which are thought to represent membrane endocytosed after hormone release[19], were also to be expected since they would thereby contain extracellular fluid with a calcium content of about 10^{-3} M.

The precipitates observed in smooth endoplasmic reticulum and microvesicles indicate that these organelles may be sites of calcium accumulation. A non-mitochondrial, ATP-dependent calcium accumulation system has been described in brain synaptosomes[17], and coated vesicles isolated from cerebral cortex are capable of calcium uptake[3]. The accompanying letter by Nordmann and Chevallier[20] demonstrates that the subcellular fractions containing predominantly microvesicles isolated from bovine neurohypophyses can accumulate calcium at concentrations appropriate for the post-stimulus recovery phase. The precipitation pattern described here therefore appears to constitute a morphological correlate of the calcium-accumulating function of microvesicles, which are not associated with any known transmitter. This agrees with evidence that the microvesicles do not alter in number with either acute[19,21], or chronic[22] stimulation of hormone release and that membrane is retrieved by vacuoles[19,21] (Fig. 1*a*), rather than by microvesicles as previously suggested[23]. The smooth endoplasmic reticulum appears to share this calcium-sequestering property and has been shown to accumulate calcium in synaptosomes[24].

The increase in microvesicles labelled with horseradish peroxidase after stimulation[25] and the presence of coated microvesicles[23] suggest that these organelles are capable of exocytosis and, indeed, clusters of microvesicles are often seen in 'synaptoid' configurations near the plasmalemma opposite pituicytes or the basement membrane (Fig. 1*a*, *c*). Calcium accumulated by microvesicles might therefore be removed from the nerve ending by exocytosis, the dispersed microvesicles near the membrane being active in this process and the clustered forms (Fig. 1*d*) representing a less active state. During stimulation, the microvesicles appear to move closer to the contact zone of the ending with the basement membrane[19] and thus their exocytosis might be activated when the gland is stimulated.

Role of corticosteroid-binding globulin in interaction of corticosterone with uterine and brain progesterone receptors

H. Al-Khouri & B. D. Greenstein

Department of Pharmacology, St Thomas's Hospital Medical School, London SE1 7EH, UK

The central actions of the steroid hormone progesterone remain an enigma. However, there is no doubt that this hormone has a vital role in the control of sexual function and behaviour in many species, including man. Furthermore, progesterone may be involved in the premenstrual and postpartum syndromes[1]. It would therefore be very useful to know the role and mechanism of action of progesterone in the brain. We now show that there are differences between progesterone receptors in brain and uterus, and possibly in the distribution of the serum progesterone-binding protein, corticosteroid-binding globulin (CBG), which may enter uterine but not brain cells.

Our understanding of the mode of action of steroid hormones was advanced greatly by the discovery of cytosolic receptor proteins which bind the steroid and migrate to the cell nucleus to modify gene expression[2]. Autoradiographic and *in vitro* binding studies have revealed that there are receptors for most classes of steroid hormone in the brain[3–8]. In this respect, progesterone continues to baffle the investigator and studies of progesterone uptake by the brain remain equivocal[6,9–12]. The problem is complicated by the extensive metabolism of progesterone in neural tissues[12] and by the presence in rat serum of CBG, which binds both corticosterone and progesterone avidly[13]. A partial solution to the problem was offered by the discovery of large amounts of highly unstable progesterone-binding components in cytosols from the rat brain, pituitary and uterus[14,15]. The complex dissociated rapidly *in vitro* even at 0 °C, and it was suggested[14] that the rapid dissociation of the complex might account for the failure of previous studies. Recently, a synthetic progestagen, promegestone (R5020, Roussel Uclaf) was introduced; this binds with high affinity to cytosolic proteins in the rat brain, pituitary and uterus[16–18]. The progestagen receptor seems to meet the requirements for a neural progesterone receptor, as it is increased after oestrogen administration in tissues rich in oestrogen receptors[17–19]. The progestagen receptor also seems to occur in the cell nucleus[20,21]. However, several important questions concerning progesterone remain unanswered. Why was the R5020 receptor not discovered using ^{3}H-progesterone? Does R5020 bind to all the progesterone receptors? There is evidence that more than one species of progesterone receptor exists[14]. Perhaps most importantly, does progesterone exert its effect in uterus and brain through the same mechanism?

In an attempt to answer some of these questions, cytosols were first prepared from the hypothalamus, midbrain and uterus of adult intact female rats as described previously[14]. The rats were perfused with 1 l of chilled normal saline before preparation, after which CBG cannot be detected in brain cytosols using sensitive binding studies[14]. After perfusion, the tissues seem normal under light microscopy and the nuclei from these tissues were capable of incorporating ^{3}H-labelled nucleotides into RNA (not shown). The cytosols were then incubated with ^{3}H-progesterone (81 Ci mmol^{-1}, Amersham; 3×10^{-8} mol l^{-1}) for 2 h at 0 °C, when apparent equilibrium between bound and free hormone is attained[14]. The ability of a variety of unlabelled steroids (progesterone, corticosterone, R5020, oestradiol-17β and 5-α-dihydrotestosterone (DHT)) to displace specifically bound ^{3}H-progesterone was tested. The experimental procedures are described fully in the legend to Fig. 1, which shows a typical result, and the results of the series of experiments are given in Fig. 2. The results are summarized as follows: (1) in the hypothalamus and midbrain cytosols, progesterone displaced ^{3}H-progesterone far more rapidly and completely than did any of the other steroids tested, including R5020. The nature of the bound radioactive progesterone remaining in midbrain cytosol after displacement with the unlabelled hormone is unclear but may reflect a very slowly dissociating binding component. (2) In the uterus, progesterone and corticosterone were equipotent in displacing rapidly and virtually completely the specifically bound ^{3}H-progesterone. Corticosterone was very much more potent in this respect in the uterus than in the brain tissues. This pattern of displacement of radioactive progesterone from uterine binding sites was also observed if binding isotherms were prepared (Fig. 1 inset). It has been shown elsewhere[14], using binding isotherms, that in brain cytosols corticosterone is a weak inhibitor of ^{3}H-progesterone binding. (3) Oestradiol-17β and DHT were significantly less potent than progesterone in displacing ^{3}H-progesterone from central and peripheral tissues ($P<0.001$; Student's *t*-test).

The possibility that unlabelled progesterone and corticosterone were displacing ^{3}H-progesterone from plasma CBG, which was not completely flushed from the tissues, was examined by carrying out immunodiffusion studies of cytosols from the rat brain areas, the anterior pituitary and the uterus, using an antibody raised to rat serum. The tissue : buffer ratios and cytosol protein concentrations for the brain areas and uterus were kept as close to each other as possible. Of the tissues tested, only uterine cytosol seemed to react with the antiserum to produce a precipitin line (Fig. 3). Whether the precipitin line shown in Fig. 3 is in fact CBG can only be clarified using the purified protein. The absence of a precipitin line does not mean that no reaction took place using cytosols from the brain, but in view of the equivalence in protein concentrations, this possibility is remote. It is more likely that CBG entered the extravascular compartment in the uterus but not the brain.

Corticosterone caused a total displacement of ^{3}H-progesterone from uterine cytosols. The displacement of ^{3}H-progesterone from uterine cytosols by R5020 must have occurred

0028-0836/80/360058—03$01.00

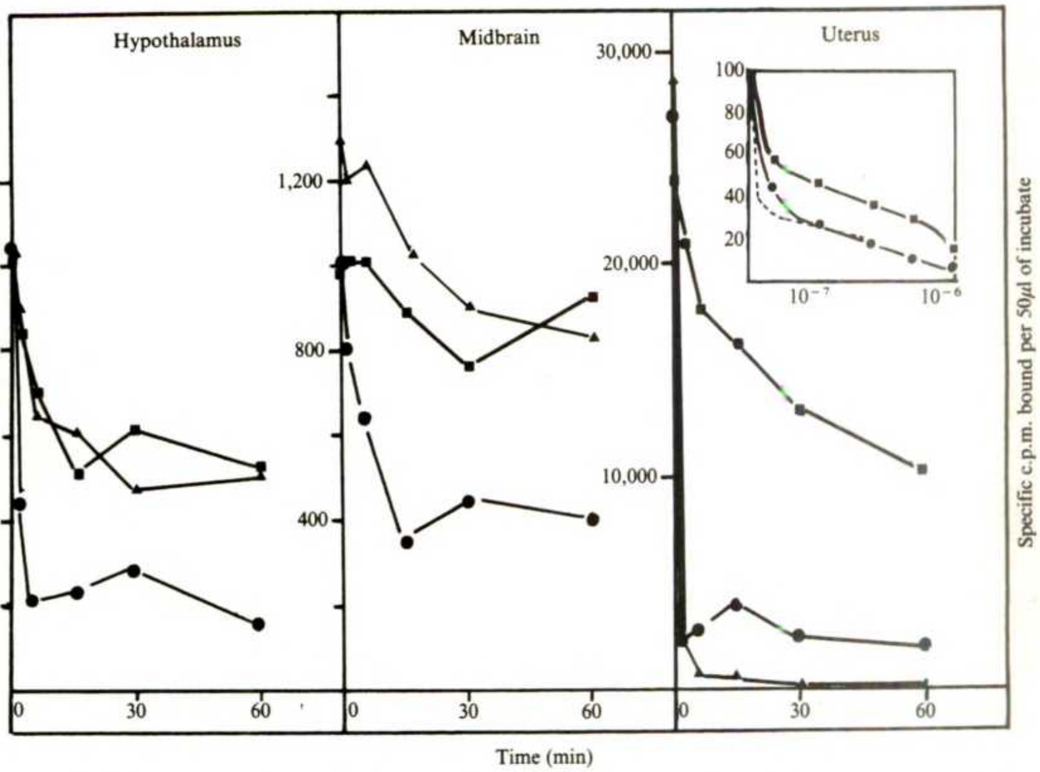

Fig. 1 Exchange of ^{3}H-progesterone and unlabelled progesterone (●), corticosterone (▲) or R5020 (■) in cytosols from the rat brain and uterus. Cytosols were incubated at 0 °C with ^{3}H-progesterone (3×10^{-8} mol l^{-1}) for 2 h, and the bound radioactivity was assessed by rapid gel filtration of 50 μl of the incubate using small columns (10×0.5 cm) of Sephadex LH20 at 1 °C (ref. 14). At time 0 (that is, after 2 h), the unlabelled hormone was added to aliquots of cytosol to give a final concentration of the competitor of 10^{-6} mol l^{-1} and the bound radioactivity was assessed various times later. Results are shown after correction for nonspecific binding of ^{3}H-progesterone. For clarity, results using progesterone, corticosterone and R5020 alone are shown (compare with Fig. 2). Abscissa, time after adding unlabelled steroid; ordinate, specific c.p.m. bound per 50 μl of incubate. Details of the scintillation spectrometry are given elsewhere[14]. Inset: binding isotherms of ^{3}H-progesterone binding in uterine cytosol in the presence of unlabelled progesterone, R5020 or corticosterone (– – – –). Cytosol was incubated with ^{3}H-progesterone (10^{-8} mol l^{-1}) alone or in the presence of varying concentrations of the unlabelled steroid for 2 h at 0 °C. Bound radioactivity was assessed as described above. Abscissa, concentration of unlabelled steroid (mol l^{-1}); ordinate, binding of ^{3}H-progesterone as a percentage of binding in the absence of unlabelled steroid.

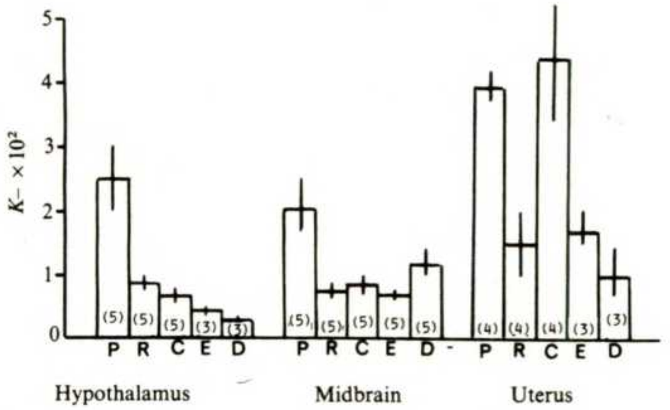

Fig. 2 Displacement of ^{3}H-progesterone from specific binding sites by unlabelled steroids in hypothalamic, midbrain or uterine cytosols. Results are expressed as the dissociation rate constant ($K-$) calculated for each steroid and tissue using the method described in Fig. 1 legend. Results are the mean ± s.e.m. and the numbers of observations are given in parentheses. $K-$ was calculated from the formula: $K- = \ln[(A^0/A)(1/t)]$, where A^0 and A are the specific binding of ^{3}H-progesterone at times = 0 and 60 min, respectively. P, Progesterone; R, R5020; C, corticosterone; E, oestradiol-17β; D, DHT.

exclusively from specific progesterone receptors in the uterus, because this steroid does not bind to CBG[16]. If corticosterone had displaced ^{3}H-progesterone from CBG only, the displacement would have been incomplete. It must be presumed, therefore, that corticosterone does displace ^{3}H-progesterone from specific progesterone receptors in the uterus, to which it apparently binds much more strongly than in the brain. The functional significance of this is unclear, but there is evidence that another glucocorticoid, triamcinolone, binds to progestagen receptors in the human prostate[22].

The importance of these results lies in the clear demonstration that progesterone, the natural hormone, displaces the tritiated steroid from the receptor in brain and uterine cytosols more potently than does R5020. Furthermore, there may be a

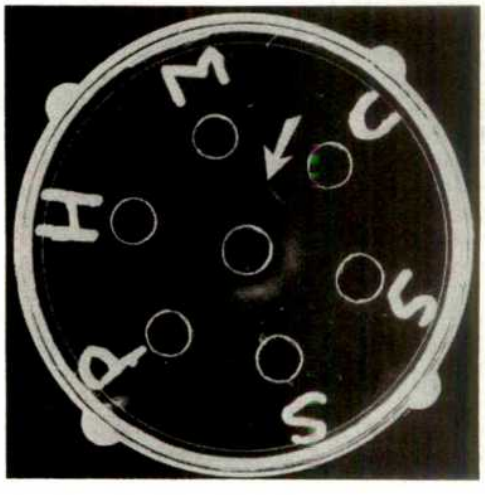

Fig. 3 Immunodiffusion of cytosols from hypothalamus (H), midbrain (M), anterior pituitary (P) and uterine (U) cytosols or rat serum (S) using antiserum raised in a rabbit to whole rat serum (Miles Yeda codes 65-038; lot R134N). To each well 3 μl of protein solution was added and this was allowed to diffuse overnight at 20 °C. The centre well contained the antiserum. The arrow indicates the precipitin line caused by the reaction between antiserum and uterine cytosol. 6.1 μg of midbrain cytosol were applied, 4.5 μg of hypothalamic and 5.0 μg of uterine cytosol.

selective movement of corticosterone carried by CBG to the extravascular and possibly intracellular compartment in the uterus but not the brain. Thus, CBG could act as a carrier receptor for corticosterone into the uterine cell, where corticosterone displaces progesterone from its receptor site. This action would have important implications in, for example, the onset of parturition. Cortisol is known to initiate parturition in the rabbit and this effect is blocked by the administration of progesterone[23]. There are thus grounds for investigating further the interactions between progesterone, corticosterone and their binding proteins in the blood and uterus with respect to the function of this tissue in reproduction.

This work was funded by an MRC project grant to B.D.G. We thank the Special Trustees of St Thomas's Hospital for assistance, Professor G. W. Bisset for reading and commenting on the manuscript, and Mrs Janice Andrews for typing the manuscript. The Ouchterlony plates used were supplied by Miles Laboratories.

Action of formamidine pesticides on octopamine receptors

Peter D. Evans

ARC Unit of Invertebrate Chemistry and Physiology, Department of Zoology, University of Cambridge, Downing Street,
Cambridge, CB2 3EJ, UK

Julian D. Gee

Pfizer Central Research, Pfizer Limited, Sandwich, Kent CT13 9NJ, UK

The formamidines are a structurally novel group of pesticides of growing importance in the control of mites, cattle ticks and certain orders of insects which have become resistant to conventional acaricides and insecticides. Their mode of action is complex with dose-dependent lethal and sublethal effects[1-3]. At sublethal levels they cause behavioural changes in the target pest species (for example in feeding and in mating behaviours), changes which are responsible for the protective effects on crops and livestock. Although many suggestions have been made for the underlying biochemical mechanism, including inhibition of monoamine oxidase activity, uncoupling of respiration and blockade of neuromuscular transmission[1], no direct evidence has been presented. Another possibility is interaction with octopamine receptors in the central nervous system[2,4,5]. We report here that the formamidine acaricide/insecticide, chlordimeform (CDM), and its demethylated derivative can mimic the actions of octopamine at the locust neuromuscular junction. This gives the clearest evidence to date of the site of action of the formamidines and indicates a novel mode of action for these pesticides.

Octopamine is one of several compounds that mimic the action of CDM in exciting certain unidentified neurones in the abdominal ganglia of the larvae of the tobacco hornworm, *Manduca sexta.* The activation of these neurones may be correlated with the increased locomotor activity and uncoordination produced in these animals by sublethal doses of CDM[2]. Octopamine, as well as CDM and some of its derivatives elicit glowing[6], and increase adenylate cyclase activity[7] in the firefly light organ[2,4,5]. Octopamine may be a neurotransmitter in the firefly light organ but in both cases definitive proof for octopaminergic neurones is lacking. However, an identified octopaminergic neurone has been shown to act at the neuromuscular junction of the locust, *Schistocerca americana gregaria*[8,9,10] and the pharmacology of the octopamine receptors has been investigated[11]. This preparation can thus provide a model system in which to study the interaction of the formamidines with identified octopamine receptors.

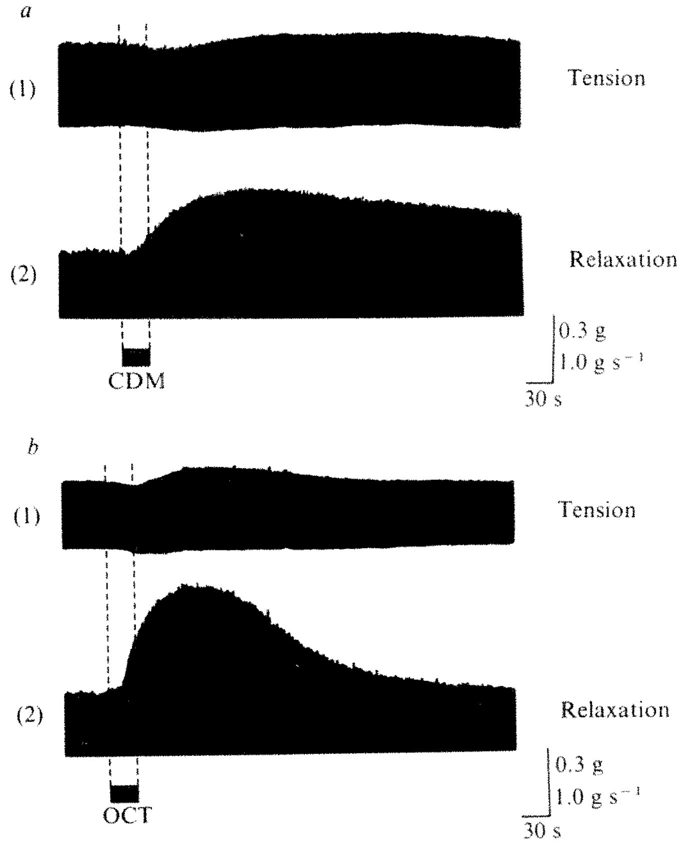

Fig. 1 Comparison of the effects of chlordimeform (CDM) (*a*) and (±)octopamine (OCT) (*b*) on the amplitude of twitch tension and rate of relaxation of twitch tension induced in the extensor tibiae muscle of the hindleg of the locust by stimulation of the slow motoneurone at 1 Hz. Traces *a*1 and *b*1 show the tension responses elicited by application of a 30 s pulse of 10 μM chlordimeform and (±)octopamine respectively. Traces *a*2 and *b*2 show the effects of the respective pulses on the rate of relaxation of twitch tension, the height of each trace being directly proportional to the rate of relaxation. Note the difference in potency and time course of the effects produced by chlordimeform and octopamine.

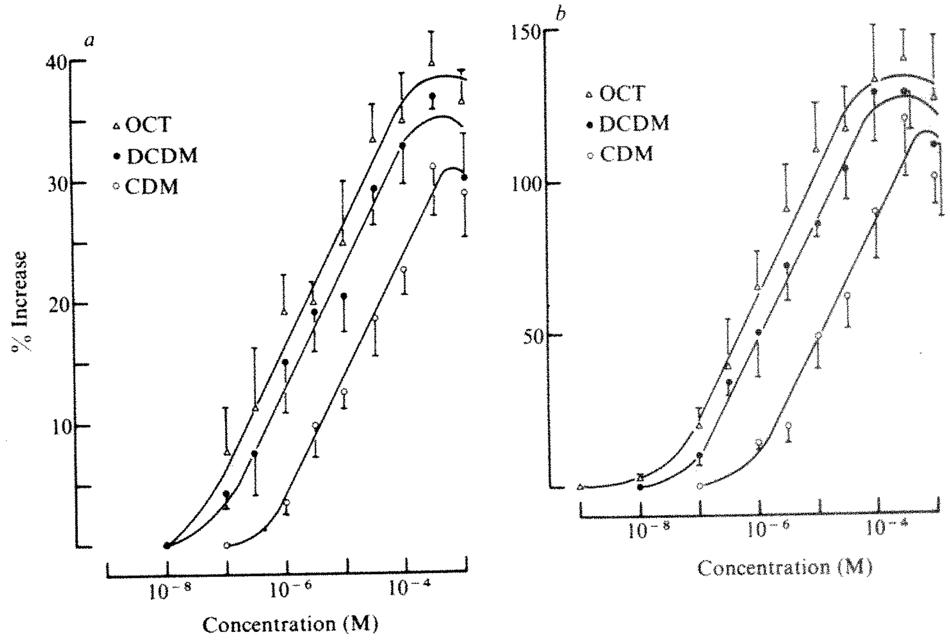
0028-0836/80/360060—03$01.00

Fig. 2 Dose–response curves for the potentiation of twitch amplitude (*a*) and relaxation rate (*b*) by octopamine (OCT), chlordime- for (CDM) and demethylchlordimeform (DCDM). The results represent the maximum percentage increases obtained at each concentration by application of a 30 s pulse of drug solution to an extensor-tibiae muscle preparation being stimulated at 1 Hz. Each point represents the mean of at least four determinations and the bars represent the s.e.m.



We stimulated repetitively the slow motoneurone (SETi) to the extensor tibiae muscle of the hindleg of *S. americana gregaria* to elicit individual muscle twitches. Using methods described previously, we continuously monitored the amplitude of muscle twitches[8,10] and their rates of contraction and relaxation[12]. Short pulses of known concentrations of the formamidines were introduced into the superfusion fluid bathing the muscle preparation and their effects compared to those produced by comparable pulses of (±)octopamine.

Figure 1 compares the effects produced by a 30 s pulse of 10 μM CDM (Fig. 1*a*) with those produced by a similar pulse of (±)octopamine (Fig. 1*b*). CDM potentiates the size of neurally evoked contractions by 10% and increases the rate of relaxation by 91%. The equivalent pulse of octopamine is more potent and increases the two parameters by 23% and 166% respectively. The time course of the effects of the two compounds differs, the effect of CDM on the relaxation rate, for example, having a half time of decay of 6.7 min whilst that for octopamine is 1.8 min in the particular examples illustrated.

A comparison of the dose–response curves for octopamine, CDM and demethylchlordimeform (DCDM) (Fig. 2*a*, *b*) reveals that the curves are parallel with peak values at 10^{-4} to 10^{-3} M for both the potentiation of twitch amplitude and the increase in relaxation rates. There is no significant difference between the curves for octopamine and DCDM and, the effects of these two compounds at saturating concentrations were not additive (data not shown). As octopamine is the only naturally occurring compound known to be capable of producing these modulatory effects at the locust neuromuscular junction[10] it is likely that CDM and octopamine are acting at the same receptor. Comparing CDM with DCDM (to which CDM is thought to be metabolized to give the lethal toxicant in CDM-poisoned cattle tick larvae[13]) half maximal percentage increases of both twitch amplitude and relaxation rate are obtained at 5×10^{-6} M for DCDM and 5×10^{-5} M for CDM. Thus DCDM is an order of magnitude more effective than CDM. This is in agreement with the rank order of potency of the phenolamines on this preparation where synephrine (the *N*-methylated analogue of octopamine) is more potent than *N*, *N*-dimethyloctopamine[10]. The structural similarities between the formamidines and the phenolamines have been pointed out and the close resemblance between DCDM and synephrine emphasized[4].

Octopamine receptors in insects are selectively blocked by α-adrenergic antagonists, such as phentolamine, in preference to β-adrenergic antagonists such as propranolol[7,9,10,11]. Phentolamine also selectively antagonises the action of CDM at the locust neuromuscular junction. Figure 3 shows an experiment where the effects of 10 μM (±)propranolol and 10 μM phentolamine are compared after an initial potentiation of twitch tension and relaxation rates by exposure of the extensor muscle to a 30 s pulse of 10 μM CDM. Propranolol has no effect, whereas phentolamine brings about a rapid reduction in both responses. Other experiments (not shown) demonstrate that phentolamine, but not propranolol, blocks the effects of CDM applied simultaneously to the extensor muscle.

We have demonstrated that both CDM and DCDM can mimic the actions of octopamine in potentiating twitch tension and increasing the rate of relaxation of tension induced in the extensor tibiae muscle. In both cases the effects are brought about by an interaction with pharmacologically characterized octopamine receptors[11]. In addition to its effects on neurally evoked tension, octopamine inhibits a myogenic rhythm of contraction and relaxation found in a bundle of specialized muscle fibres in the extensor tibiae muscle of the locust hindleg[9,14]. This effect is also mimicked by CDM and DCDM (not shown). The frequency of the myogenic contractions is reduced by 50% by exposure to 10^{-6} M CDM for 10 min.

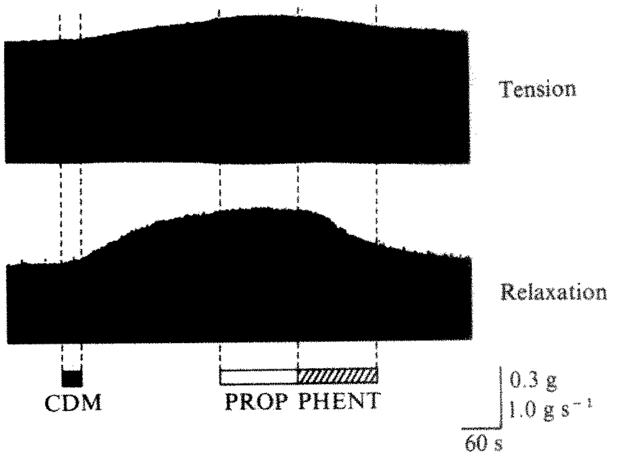


Fig. 3 The effect of blocking agents on the responses of the extensor tibiae muscle to a 30 s pulse of 10 μM chlordimeform (CDM). The top trace indicates the tension responses recorded from the muscle by stimulating the slow motoneurone at 1 Hz and the bottom trace shows the corresponding changes in relaxation rates. (±)propranolol (PROP) 10 μM was applied for a 2-min period indicated by the open bar and 10 μM phentolamine (PHENT) for a 2-min period indicated by the hatched bar.

The effects of the formamidines on neuromuscular transmission in the locust parallel those on the firefly light organ in several respects. In both cases DCDM is more effective than CDM, and their actions are blocked by phentolamine[4]. In the studies on the firefly light organ, however, the exact concentration of the formamidines superfused over the preparation was not reported and the effects of α- and β-adrenergic blocking agents were not compared. The effects of the formamidines are also much longer lasting than those of octopamine in both the firefly and locust preparations. It has been hypothesized that this might be due to a greater tissue solubility of the formamidines which would slow down their penetration to the receptors and maintain an excitatory concentration of the compounds close to the receptors for a longer time than an equivalent dose of octopamine[4]. The longer half-time of decay of the effects of CDM, however, suggests that the formamidines have a longer half-time of receptor occupancy than octopamine.

We thank Dr M. V. S. Siegler for critically reading the manuscript and Drs L. L. Murdock and R. M. Hollingworth for providing a sample of DCDM.

Sodium channels in plasma membranes can be blocked by a large variety of toxins[1] and local anaesthetics[2]. This property, however, is not confined to relatively large molecules. For instance, extracellularly applied small ions like hydrogen may also prevent the passive transport of permeant cations across open Na^+ channels[3–6]. A typical feature of this phenomenon[3,5] is that the blocking action of hydrogen is gradually relieved by increasing the voltage applied across the membrane. Although in the frog skeletal muscle there is no clear evidence for a similar intracellular action[7], we report here for the squid giant axon remarkable effects on the ionic permeability of Na^+ channels when the internal perfusate contains an excess of protons. Analysing the action of low pH inside and outside the fibre in terms of a kinetic model[3], we could conclude that Na^+ channels in squid axons are controlled by two independent groups: one with an apparent pK_a of 4.6 and the other with pK_a 5.8, the former feeling one-fifth of the applied membrane potential, the latter three-quarters. As with pharmacological agents[8], we also show that the voltage-dependence of the H^+ blockage is not affected by the presence of the inactivation gate.

Figure 1 shows computer records of Na conductance at normal and low intracellular pH (pH_i) obtained from giant axons of the squid *Loligo vulgaris* perfused and voltage-clamped by the method of Wanke *et al.*[9]. The traces on the right were recorded after 90 s of internal perfusion at pH_i 5.3 and were found to reverse by returning to normal conditions (pH_i 7.2). Applications of low pH_i produce remarkable alterations to both the time course and voltage-dependence of the Na^+-channel conductance. The peak conductance, g^p_{Na}, is strongly depressed below 60 mV while at higher depolarizations the amount of depression is gradually reduced by raising the voltage (Fig. 2*a*). Significantly, at 220 mV the difference of g^p_{Na} at pH_i 7.2 and 5.3 is less than 20% of the control, with a tendency to diminish further at higher potentials. As shown in Fig. 2*a*, lower pH_i has even more marked effects on the shape of $g^p_{Na}(E)$, supporting the idea that the block of g_{Na} by hydrogen ions follows the titration property of an acidic sidegroup. Peak conductance relative to the control at $E = 100$ mV is plotted in Fig. 2*d*.

Figure 1 gives a clear indication that the voltage-dependence of the H^+ block is not related to the action that pH_i has on the gating of both the activation and inactivation processes[10]. This view is supported by the observation that at the end of the g_{Na} records ($t = 4$ ms), when fast Na^+ inactivation is almost complete, the change in g_{Na} with increasing voltage parallels that of g^p_{Na} in the range 140–220 mV. A direct confirmation came from a series of experiments in which the effects of low pH_i were tested in axons treated with the enzyme mixture Pronase[11], which removes selectively the fast inactivation gate of Na^+ channels. As expected, in four trials the effects were similar to those with intact axons (Fig. 2*b*). Several other controls were done to verify that the H^+ blockage was genuine. On a total of more than 30 axons, replacements of the internal ionic composition, type and amount of buffers yielded results analogous to those in Fig. 1.

Although a rigorous treatment of the present data would have required the use of a complete four-barrier model for the Na^+ channel[12], we found it more profitable in our preliminary studies to use the simpler two-barrier model proposed by Woodhull[3]. The model postulates the existence of a receptor site for H^+ ions located part of the way across the Na^+ channel, having the following properties: (1) the rates of hydrogen binding and unbinding are exponential functions of voltage as in Eyring rate theory; (2) an H^+ ion can reach the site from either side of the membrane according to the scheme

$$H_{out} \underset{b_{-1}}{\overset{[H_o]b_1}{\rightleftharpoons}} \text{H-site} \underset{[H_i]b_{-2}}{\overset{b_2}{\rightleftharpoons}} H_{in}$$

where b_i indicate the voltage-independent components of the

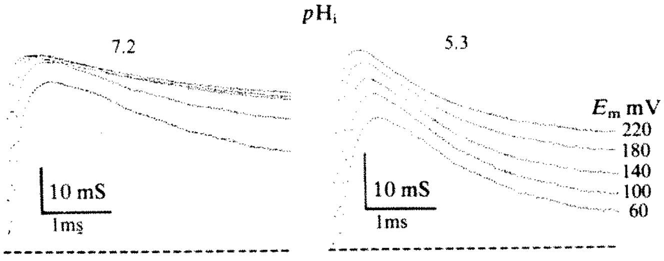

Fig. 1 Time course of Na conductance at neutral (left) and acid (right) pH_i. The membrane was hyperpolarized to −90 mV for 180 s to remove slow inactivation and then depolarized to the test potential indicated. Successive stimuli were separated by 1 s. Positive feedback was used. Data were obtained from current records corrected for TTX-insensitive currents after division by the driving force $E - E_{Na}$. E_{Na} was −26 mV. During stimulation, the periaxonal accumulation of Na^+ ions was controlled by brief hyperpolarizations[9]. In this way E_{Na} was found to increase by less than 3 mV. Internal solutions (mM): 200 Na^+, 117 F^- and $H_2PO_4^-$ (pH_i 7.2) or 200 Na^+, 80 F^- and 45 citric acid (pH_i 5.3). External bath (mM): 109 Na^+, 326 tetramethylamine, 10 K^+, 20 Tris, 10 Ca^{2+}, 40 Mg^{2+}, 555 Cl^- (pH_o 8). Temperature 2 °C.

0028–0836/80/360062—02$01.00

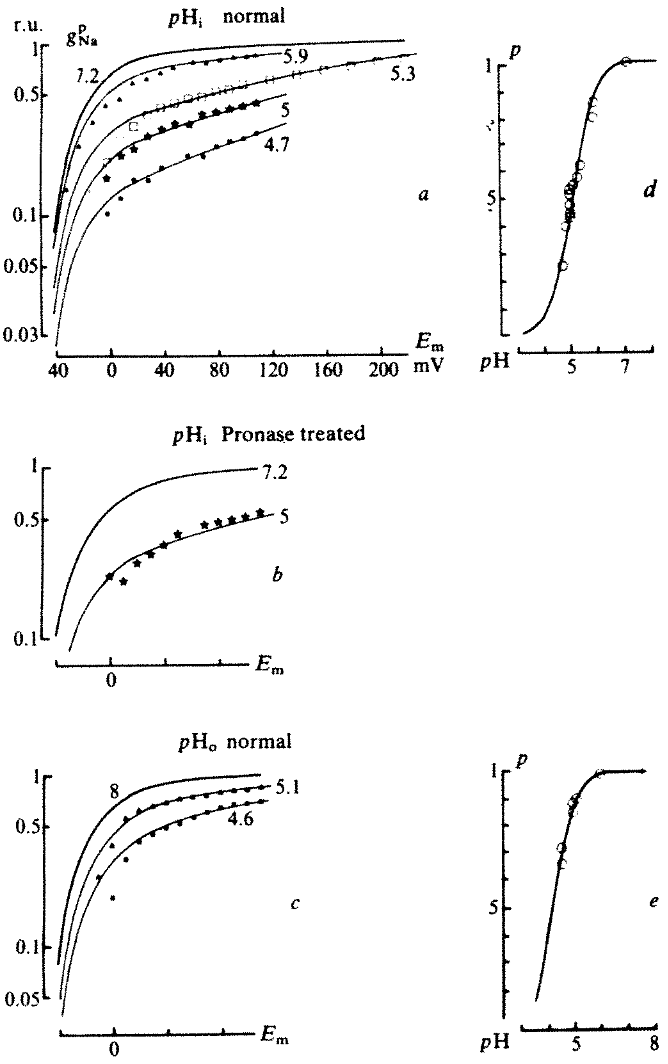

Fig. 2 Action of low pH$_i$ on peak sodium conductance, $g_{Na}^{P}(E)$. *a*, *b* and *c*, symbols indicate experimental data. Solid lines at control pH represent an average from seven axons at pH$_i$ 7.2 and pH$_o$ 8. Continuous lines at test pH are the product of the control curves and the fraction of unblocked channels, *p*, as derived by Woodhull[3]:

$$\left[1+\frac{[H_o]+[H_i]b_{-2}/b_1 \exp FE/2RT}{b_{-1}/b_1 \exp \delta FE/RT(1+b_{-2}/b_1 \exp -FE/2RT)}\right]^{-1} \quad (1)$$

where δ is the fraction of the potential drop crossed on approaching the site from the outside ; b_i are rate constants (see text) and *F*, *R*, *T* have their usual meaning. Solid lines in *c* at pH$_o$ 5.1 and 4.6 were obtained by setting in equation (1): $\delta=0.20$, $b_{-2}/b_1=0.01$ and $b_{-1}/b_1=2.4\times10^{-5}$. Corrected data and standard solutions at pH$_i$ 7.2 and pH$_o$ 8 are the same as those of Fig. 1. Internal solutions of low pH all contained 200 mM Na$^+$ and 45 mM of the following buffers: $H_2PO_4^-$ (pH$_i$ 5.9), citric (5.3, 5 and 4.7). External solutions of low pH had the same ionic content as in Fig. 1 except for the buffer which was 20 mM citric acid for pH$_o$ 5.1 and 4.6. The pronase-treated fibre was perfused for 100 s with a solution containing 2 mg ml^{-1} of enzyme at pH$_i$ 9.9. *d*, *e*, Internal and external pH dependence of the quantity *p* at $E_m=100$ mV. Each dot represents a different axon. Solid lines through data points are derived from equation (1) by setting $E_m=100$ mV.

rate constants and [H$_i$], [H$_o$] the concentrations of protons inside and outside the fibre.

As shown in Fig. 2, the model allows an evaluation of the fraction of unblocked channels, *p*, in terms of three independent parameters: δ, b_{-2}/b_1 and b_1/b_{-1} (see Fig. 2 legend). For the internal block, good fits of the g_{Na}^{P} curves at low pH$_i$ were obtained by setting: $\delta=0.75$, $b_{-2}/b_1=1$ and $b_1/b_{-1}=1.6\times10^{-6}$. Few points at low depolarizations are systematically lower than the theoretical predictions, suggesting the existence of a small unexpected shift of $g_{Na}^{P}(E)$ toward depolarizing voltages. Interestingly, with the same set of parameters we could also fit the pH dependence of the block shown in Fig. 2*d*.

With the view of testing further the validity of the Woodhull's model in squid axons, we reinvestigated the action of low extracellular pH (ref. 13), pH$_o$, on g_{Na}^{P}. As shown in Fig. 2*c*, *e*, low pH$_o$ is apparently less effective in blocking open Na$^+$ channels than a corresponding low pH$_i$ value, suggesting the existence of different titratable groups on each side of the channel: one external with an apparent pK$_a$ of 4.6 and one internal with pK$_a$ 5.8. It is also evident from Fig. 2 that the reduction of g_{Na}^{P} at pH$_o$ 4.6 is smaller than that reported by Carbone *et al.* for unperfused squid axons (probably due to the present improved pH$_i$ control; compare Fig. 3b in ref. 13). Lowering the pH of the external bath is known to decrease the intracellular pH (ref. 14). Thus, it is very likely that in intact fibres the effects of low pH$_o$ superpose partly on those of low pH$_i$, implying that axons with uncontrolled pH$_i$ might be more sensitive to changes of pH$_o$. Although in frog nodes[3] and skeletal muscles[5] the apparent pK$_a$ of the blocking site is systematically higher than the value found here (5.3 against 4.6 for perfused axons), our results indicate a substantial similarity in the external properties of Na$^+$ channels for the three types of membranes.

The presence of an acid group inside the channel accessible from the axoplasmic region is in good agreement with the finding that other pharmacological agents, such as pancuronium[15] and 9-aminoacridine[8] (9-AA), affect open Na$^+$ channels of squid axons in a voltage-dependent manner. Both molecules are positively charged at pH$_i$ 7.2 and have a sufficiently high affinity for their binding site ($K_a=6.2\times10^{-5}$ M and $\delta=0.5$ for 9-AA) to suggest that the acid group in question could be identified with part of their receptor site. Experiments concerning the pH dependence of their rate of action would certainly clarify this theory. Interestingly, the site is hardly accessible to high concentrations of tetrodotoxin (TTX)[16] even when the toxin is applied intracellularly at various pH$_i$ values (own observation). This promptly suggests that the molecular arrays surrounding the internal and the external acid groups might be remarkably different.

To our knowledge there are no other reports indicating the existence of an intracellularly negative group within the Na$^+$ channel. Recently, Nonner *et al.*[7] have shown that in the frog skeletal muscle low pH$_i$ does not produce significant reductions of the peak sodium permeability. They also showed that some inactivation-removing agents previously tested in squid axons have different effects when applied to the muscle membrane. This indicates that we should not make generalizations based on the present findings and suggests that although Na$^+$ channels of various plasma membranes have similar external regions, they might differ substantially in the unexposed internal part.

We thank Drs F. Conti, B. Hille and H. Meves for helpful suggestions on a preliminary version of this work.

Solubilization of the choline transport system and re-incorporation into artificial membranes

R. G. King & R. M. Marchbanks

Department of Biochemistry, Institute of Psychiatry,
London SE5 8AF, UK

The carrier-mediated transport of choline has been described in several types of cell[1–3] and at isolated synaptic terminals[4]. The operation of the carrier seems to be a rate-controlling factor for the synthesis of acetylcholine at the synaptic terminals that release this neurotransmitter[5]. The molecular mechansism by which the carrier transports choline is unknown and difficult to investigate because at present it can only be studied in the complex environment of the natural membrane in which it is situated. Furthermore, such studies are hampered by the results of metabolic activity inside the cell itself. The resolution of these difficulties by the separation, purification and examination of carriers in defined systems is hindered by the problem of assaying its activity during the purification procedure. We describe here the separation of the choline carrier from the membrane and its re-incorporation into unilamellar liposomes with retention of its functional activity, thus enabling its purification and examination in isolation to be undertaken.

The starting material used was synaptic plasma membrane of guinea pig cerebral cortex produced from hypo-osmotically shocked synaptosomes (nerve ending particles) by the procedure of Jones and Matus[6]. Membrane material was solubilized with cholate using a modification of the procedure of Kagawa and Racker[7], but as in Racker's original method[8], no urea was present, and 1 mM dithiothreitol was added. Insoluble material was removed by centrifugation at 100,000*g* for 30 min.

A mixture of purified lipids of approximately similar composition to synaptic plasma membrane[9] (40% phosphatidylcholine, 30% phosphatidylethanolamine, 20% cholesterol, 10% phosphatidyl serine w/w) were dispersed by ultrasonication, added to the cholate extract (3 mg ml^{-1} lipids, 2 mg ml^{-1} protein) and dialysed[7]. As dialysis proceeds, unilamellar liposomes are formed and these incorporate proteins and lipids from the original cholate extract. Choline transport was measured by observing the uptake of ^{3}H-choline, the liposomes having been separated from the incubation medium by Millipore filtration followed by two washes.

As shown in Fig. 1, ^{3}H-choline uptake by the liposomes is reduced by the presence of saturating concentrations (10 mM) of nonradioactive choline chloride during the first 4 min of uptake: this effect is not seen after periods of 30 min or more. A comparison with the uptake into liposomes prepared from pure lipid alone cannot be made on a protein basis, but the ratio can be expressed as the fraction of equilibration value or on a phospholipid basis. As Table 1 shows, it is the incorporation of membrane extract into the liposomes that increases the rate of choline uptake and confers saturability. Hemicholinium had no statistically significant effect on pure lipid liposomes.

Table 1 Comparison of ^{3}H-choline uptake by pure lipid liposomes and liposomes made with lipid and cholate-solubilized extract of synaptic plasma membrane

	Fraction of equilibrated value (±s.e.m.(*n*))	
	In 4 min	In 60 min
Lipid alone	0.26±0.05(8)	0.79±0.09(8)
Lipid alone+10 mM choline chloride	0.30±0.04(8)	0.80±0.12(8)
Lipid+extract of s.p.m.	0.49±0.05(6)	0.78±0.08(6)
Lipid+extract of s.p.m.+10 mM choline chloride	0.32+0.03(6)	0.75±0.10(6)

Liposomes were prepared as described in the text, and uptake experiments carried out as described in Fig. 1 legend. Pure lipid liposomes were prepared in the same way with cholate but without the addition of cholate-solubilized extract of synaptic plasma membrane (s.p.m.). Phospholipid content of the liposomes was measured, and the initial rate of uptake expressed on a basis of phospholipid content was 0.46 pmol per mg phospholipid per min (lipid and extract of synaptic plasma membrane) and 0.20 pmol per mg phospholipid per min (lipid alone); both measurements were made at a choline concentration of 1 μM.

To guard against the possibility that ^{3}H-choline is bound to the liposomes, 10 mM choline was present in the washing solution in all experiments. A further check is that trans-activation of influx can be demonstrated in the protein-loaded liposomes. It has been shown in many transport systems, including that for choline[3,5], that preloading with the transported substance actually increases the uptake of that substance. If binding were responsible for the results of Fig. 1, preloading the liposomes with choline chloride would be expected to diminish ^{3}H-choline uptake. However, as shown in Table 2, preloading with cold choline caused completely the reverse. The demonstration in Table 2 that influx is increased by preloading with choline also shows that an important feature of the *in vivo* transport of choline is retained in the artificial membrane system.

Hemicholinium-3 is a specific inhibitor of choline transport[10]. It has an inhibitory effect (Table 2) on choline uptake in protein-containing liposomes, although we found some variability in its effectiveness. Choline transport is known to be sensitive to the Na$^+$ and K$^+$ gradients across the membrane[3,4]. Whether or not this is due to a requirement for sodium co-transport, an inwardly directed negative electrical gradient, or some other mechanism, is unknown. Liposomes were prepared in a predominantly KCl medium and then transferred to a larger volume of predominantly NaCl medium so as to mimic the ion gradient found normally. It was found that liposomes prepared in KCl had

Table 2 Effects of hemicholinium, preloaded choline and valinomycin on uptake of ^{3}H-choline by liposomes prepared with cholate extract of synaptic plasma membrane

	Initial rate as % control±s.e.m.(*n*)
Liposomes+10 mM choline chloride	7±12(8)
Liposomes+100 μM hemicholinium	72±10(8)
Liposomes preloaded with 2 μM choline chloride	132±16(8)
Liposomes preloaded with 10 μM choline chloride	192±24(8)
Liposomes preloaded with 15 μM choline chloride	208±32(8)
Liposomes made in K$^+$ medium and then transferred to Na$^+$ medium:	
Liposomes+10 mM choline chloride	52± 8(10)
Liposomes+8 μM valinomycin	155±22(10)
Liposomes+8 μM valinomycin+10 mM choline chloride	104±18(10)

Liposomes were prepared as described in the text (those made in K$^+$ medium were prepared in the same way, except that 100 mM KCl replaced 100 mM NaCl in all solutions). Uptake over 30 s was measured as in Fig. 1, except that the liposomes were added to a larger volume (360 μl) of NaCl-based dialysis medium containing 2–3 μCi ^{3}H-choline. Preloading was by incubation with choline chloride until equilibrium was reached (control liposomes incubated as well). External choline concentration during ^{3}H-choline uptake was 5 μM (except where 10 mM choline was present). The two control groups of liposomes were in the medium as described above, but with none of the additions, and the rates of uptake were: 1.9 pmol per mg protein per min (upper part) and 3.0 pmol per mg protein per min (lower part), both at a choline concentration of 5 μM.

0028-0836/80/360064—02$01.00

approximately 50% greater initial rate of uptake of ^{3}H-choline than liposomes prepared in a predominantly NaCl medium. Also, valinomycin (which could be expected to produce a potential across the membrane by specifically increasing its permeability to K^+) caused an increased uptake of ^{3}H-choline by the liposomes; this, however, was not inhibited by 10 mM choline chloride. The presence of certain other substances in the external solution, including 2 mM $MgCl_2$, 1 mM $CaCl_2$ and 3 mM MgATP, had no statistically significant effect; however, we have not tested the effects of different concentrations of these substances inside the liposomes.

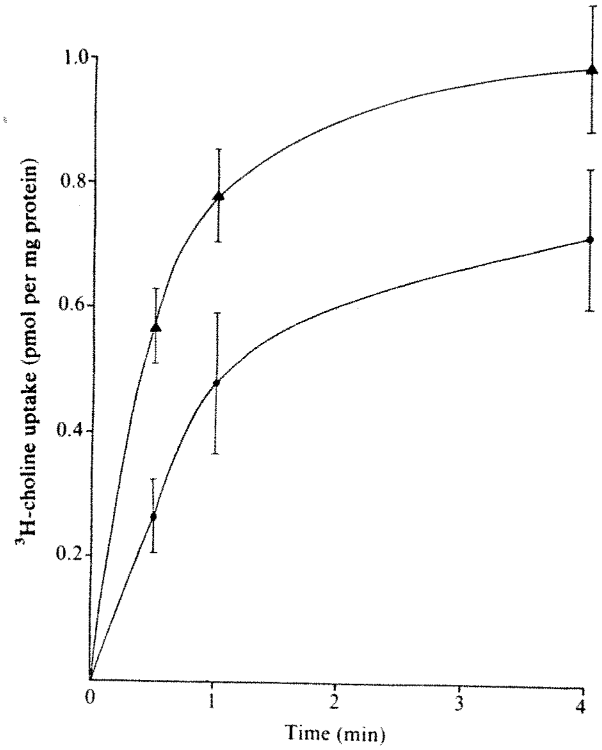

Fig. 1 Time course of uptake of ^{3}H-choline by liposomes containing membrane extract. Liposomes prepared as described in the text were preincubated for 30 min at 37 °C, and then 140-μl samples were added to 70 μl of dialysis fluid (37 °C) containing 1-2 μCi ^{3}H-choline (1 μM). After the required time of incubation (37 °C), 200 μl was placed in 5 ml of ice-cold filtering solution (100 mM NaCl, 10 mM Tris–HCl and 10 mM choline chloride, *p*H 7.4), immediately filtered on Millipore filters (0.22 μm pore diameter) and then washed twice with 10 ml of filtering solution. The order of filtering was randomized because pressure differences in the apparatus affect the blank value. Zero points were obtained by adding the liposome suspension directly to the filtering solution (which already contained ^{3}H-choline) and filtering immediately. Filters were dried, counted in 10 ml of scintillant and uptake of ^{3}H-choline determined from the value of the mean of at least four filtrations, minus the zero value. Protein entrapped on the filters was measured directly[13]. ▲, Without 10 mM choline; ●, with 10 mM choline. Vertical bars show s.e.m of four filtrations.

The effects of varying concentrations of external choline chloride on the uptake of ^{3}H-choline were investigated and it was found that the uptake was saturable, with a half-maximal concentration of 50–100 μM. Double-reciprocal plots of influx against choline concentration showed an inflection at a choline concentration of about 4 μM. Although we cannot explain this phenomenon, it has also been reported[11] in isolated synaptosomes.

In cerebral cortex synaptosomes the initial rate of choline influx at a choline concentration of 1 μM is 10–20 pmol per min per mg protein; the rate in protein-containing liposomes is 0.5–1.0 pmol per min per mg protein, so that only 5–10% of the native activity is retained. This may be because only a fraction of the total carrier has been extracted; alternatively, some may be denatured, some may be incorporated into the membrane in the wrong orientation or, as occurs with erythrocyte glucose arrier[12], only a small proportion of the liposomes contain a functional carrier molecule. The latter proposal would also explain why inhibition of ^{3}H-choline influx by 10 mM choline is only seen during the initial phases of uptake. Whatever the explanation, the solubilized carrier when incorporated into liposomes has retained the important properties of saturability, hemicholinium sensitivity and trans-activation.

A ribosomal protein mediates eIF-2 phosphorylation by interferon-induced kinase

Kenzo Ohtsuki, Masataka Nakamura, Tsuneaki Koike, Nakao Ishida & Samuel Baron*

Department of Bacteriology, Tohoku University School of Medicine, Sendai 980, Japan
*Department of Microbiology, University of Texas Medical Branch Galveston, Texas 77550

We have previously reported that treatment of mouse L cells with interferon (IFN) induces a reduction of initiation factor (eIF-2) activity (ternary complex formation of eIF-2 with Met-tRNA$_f$ and GTP)[1], and that the reduction of eIF-2 activity involves the phosphorylation of eIF-2 by an IFN-induced protein kinase[2]. In addition, we considered that the reduction of eIF-2 activity induced by the kinase (cyclic AMP-independent protein kinase) may be accompanied by the phosphorylation of some intermediary factor(s)[2]. This possibility was supported by early reports that at least two ribosomal proteins (of molecular weights (MWs) 35,000–38,000 and 64,000–67,000) of mouse L cells[3–5] and cellular proteins of Ehrlich ascites tumour cells[6] are highly phosphorylated by IFN treatment. Recently, we and others have purified IFN-induced protein kinases from different cells treated with IFN[2,3,7–9]. These purified kinases show several similarities. The reports suggested that the IFN-induced kinase may be responsible for the phosphorylation of the ribosomal proteins (MWs 35,000–38,000 and 65,000–67,000) and that the phosphorylation of these proteins by the kinase may be associated with the reduced eIF-2 activity in IFN-treated cells[2–4,8,9]. A similar inhibitory mechanism of eIF-2 activity has been demonstrated in rabbit reticulocyte lysates[10–15]. The present study was undertaken to purify a ribosomal protein [MW 65,000 (65K)] from mouse L cells and to examine the effect of the protein on eIF-2 activity, and also on the binding of the ternary complex to the 40S ribosomal subunit. We found that the eIF-2 activity was greatly reduced when both eIF-2 and the ribosomal protein were incubated with IFN-induced kinase *in vitro*. Available evidence suggests that the inhibitory mechanism of eIF-2 activity induced by the kinase *in vitro* may involve phosphorylation of the ribosomal proteins [a small subunit (MW 38,000) of eIF-2 and 65K ribosomal protein] by the IFN-induced kinase.

0028-0836/80/360065—03$01.00

A 65K ribosomal protein was purified from 0.5 M KCl ribosomal extracts of mouse L cells as described in Fig.1. SDS-polyacrylamide gel electrophoresis showed that the purified 65K ribosomal protein was a single polypeptide. Table 1 shows that the 65K ribosomal protein functioned as a phosphate acceptor of IFN-induced kinase *in vitro*; however, the substrate activity of the protein was more than 50% of that of purified eIF (98% pure). About 80 pmol of the ribosomal protein were phosphorylated in these conditions. In addition, double-stranded (ds) RNA (poly(I)·poly(C), 100 ng ml^{-1}) stimulated about 3.2 times the phosphorylation of the ribosomal protein by the kinase *in vitro*. The phosphorylation of the 65K ribosomal protein and eIF-2 was confirmed by SDS-polyacrylamide gel electrophoresis (data not shown). No protein kinase activity in the final preparation of 65K ribosomal protein was detected.

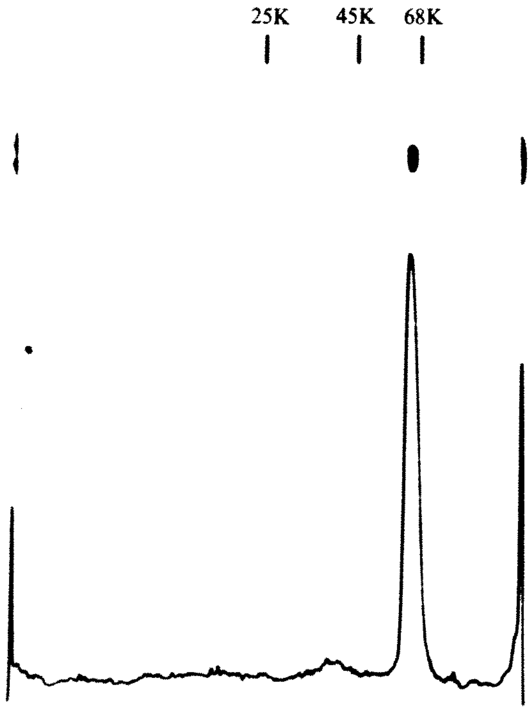

Fig. 1 Purification of the 65K ribosomal protein from 0.5 M KCl extracts of mouse L cells and SDS-polyacrylamide gel electrophoresis of the protein, 0.5 M KCl extracts from ribosomes of mouse L cells were used for the purification of 65K ribosomal protein because early reports showed that at least two proteins (MWs 35,000–38,000 and 64,000–67,000) are highly phosphorylated in the cell extracts of IFN-treated cells and this protein phosphorylation is greatly stimulated by the addition of dsRNA (poly(I)·poly(C), 10–200 ng ml^{-1})[2,3,6]. The 0.5 M KCl extract (about 300 mg crude protein) was passed through a Sephacryl S-200 column (2.2 × 76 cm) previously equilibrated with buffer A [20 mM Tris-HCl (*p*H 7.5) containing 2 mM dithiothreitol, 50 mM KCl and 5% glycerol] to purify a 65K ribosomal protein which was highly phosphorylated by IFN-induced kinase *in vitro*. The column was eluted with buffer A and 1.0 ml of fraction was collected. The fractions (MWs ~60,000–70,000) were pooled and concentrated with solid ammonium sulphate (60% saturation). After dialysis against buffer A (overnight at 4°C), the fraction (~60 mg protein) was further purified by a DEAE-cellulose column (1.4 × 12 cm) previously equilibrated with buffer A. The column was eluted with a linear gradient from 0.05 M to 0.5 M KCl in buffer A (50 ml). DEAE-cellulose column chromatography showed two distinct protein peaks (flow-through fraction and the 0.08 M–0.35 M KCl fraction). Over 70% protein kinase activity of the Sephacryl S-200 fraction was detected in the flow-through fraction, whereas the stimulating effect of dsRNA (poly(I)·poly(C), 100 ng ml^{-1}) on substrate activity for the kinase was detected in the fractions which were eluted between 0.1 M and 0.15 M KCl. Moreover, the activity of cyclic AMP-independent protein kinase was eluted between 0.15 M and 0.2 m KCl. The fractions with substrate activity for the kinase were pooled and immediately concentrated by vacuum dialysis against buffer A to 0.5 ml. Finally, the DEAE-cellulose fraction (total 15 mg protein) was purified by preparative gel electrophoresis. The protein with substrate activity for the kinase in the gel was extracted with 0.5 M KCl extracts from the ribosomes of mouse L cells with a protein yield of less than 1%. SDS-polyacrylamide gel electrophoresis[16] showed that the purified ribosomal protein was a single polypeptide with a MW of 65,000, as estimated from the marker proteins.

We tested the effect of 65K ribosomal protein on eIF-2 activity. Less than a 9% reduction was detected when purified eIF-2 (98% pure) was incubated with the kinase in the absence of the ribosomal protein, whereas the activity was greatly reduced when both eIF-2 and the ribosomal protein were preincubated with the kinase. No reduction of eIF-2 activity occurred when both proteins were incubated without the kinase (Table 2). In addition, no reduction of eIF-2 activity occurred when ATP or Mg^{2+} was omitted from the reaction mixture. The effect of ATP was not substituted by GTP and high levels of Mg^{2+}(>5 mM) prevented the reduction of eIF-2 activity induced by the phosphorylation of these two proteins (eIF-2 and 65K ribosomal protein) by the kinase *in vitro* (data not shown). Low levels of dsRNA stimulated this reduction, but it was prevented by aminopurine which is an inhibitor of the kinase[2,17]. These results showed that the phosphorylation of these two ribosomal proteins by the kinase *in vitro* resulted in the reduction of eIF-2 activity.

Table 1 Effect of dsRNA on phosphorylation of eIF-2 or 65K ribosomal protein by IFN-induced kinase *in vitro*

Additions	[γ-^{32}P] ATP into the substrate (pmol)
None	0.1
eIF-2	15.0
eIF-2 + dsRNA	31.3
65K ribosomal protein	8.9
65K ribosomal protein + dsRNA	28.5
65K ribosomal protein + eIF-2	22.6
65K ribosomal protein + eIF-2 + dsRNA	54.0
65K ribosomal protein + aminopurine	3.8

The reaction mixture (0.1 ml) contained 20 mM Tris-HCl (*p*H 7.5), 4 mM dithiothreitol, 1 mM magnesium acetate, 0.1 mM [γ-^{32}P] ATP (3,000 c.p.m. pmol^{-1}), 10 μg of bovine serum albumin (BSA), 0.5 μg of IFN-induced kinase and a substrate [5 μg of purified eIF-2 (98% pure) or 5 μg of 65K ribosomal protein]. The reaction mixture was incubated for 10 min at 37 °C in the presence or absence of dsRNA (poly(I)·poly(C), 100 ng ml^{-1}) or 1 mM aminopurine. The reaction was stopped by the addition of 0.5 ml of 20% trichroloacetic acid (TCA) and 0.5 ml of 0.2 M sodium pyrophosphate containing 1 mg ml^{-1} of BSA. The radioactivity of the TCA precipitate was determined as previously reported[2].

In the presence of GTP and Met-tRNA$_f$, eIF-2 forms the ternary complex, Met-tRNA$_f$–eIF-2–GTP, which binds to the 40S ribosomal subunit[13,15]. We tested the effect of 65K ribosomal protein on the binding of the ternary complex to the 40S subunit. The complex (ternary complex–40S subunit) formed was analysed by 5–30% (w/v) sucrose density gradient centrifugation. Figure 2 shows that the complex formation was greatly reduced when both eIF-2 and 65K ribosomal protein were preincubated with the kinase in the presence of ATP (0.1 mM) and Mg^{2+} (1 mM). The reduction of the complex formation did not occur if ATP or Mg^{2+} was omitted from the reaction mixture, as described in the reduction of eIF-2 activity induced by the kinase. These results suggested that the phosphorylation of two ribosomal proteins by the kinase results in the reduction of the binding of the ternary complex to the 40S subunit.

The present finding that the reduction of eIF-2 activity involves phosphorylation of both eIF-2 and 65K ribosomal protein by IFN-induced kinase *in vitro* is at least partially consistent with other observations which are: (1) at least two ribosomal proteins (MWs 35,000–38,000 and 64,000–67,000) which are highly phosphorylated by IFN treatment[3–5]; (2) low levels of dsRNA stimulated the phosphorylation of a small subunit (MW 38,000) of eIF-2 and 65K ribosomal protein by the kinase *in vitro*[2,4,17,18]; and (3) in rabbit reticulocyte lysates, the eIF-2 activity is inhibited by a haem regulatory inhibitor (HRI, cyclic AMP-independent protein kinase)[10–12]. However, it has also been reported that no inhibition occurs when highly purified eIF-2 is used[19,20]. In these conditions, HRI phosphorylates only a small subunit of eIF-2, thereby indicating that the phosphorylation of a small subunit of eIF-2 alone is not sufficient to alter the ternary complex forming activity of eIF-2[19,20]. Our data and indirect evidence in the literature on reticulocyte lysates strongly suggest that the 65K ribosomal protein may be the intermediary factor which is responsible for the reduction of eIF-2 activity induced by IFN treatment or IFN-induced kinase *in vitro*. In addition, the recent evidence of a steric difference of a 5′-terminal structure between viral and eukaryotic cell mRNAs suggests that the phosphorylation of ribosomal proteins (eIF-2, 65K ribosomal protein and others) by IFN-induced kinase may be responsible for the discrimination of initiation complex formation between viral and eukaryotic cell mRNAs[21]. We are now carrying out comparative and analytical studies on the biological and physicochemical properties of the 65K ribosomal protein from mouse L cells treated with IFN and the cells infected with viruses.

Table 2 Effect of 65K ribosomal protein on eIF-2 activity

Preincubation	[^{35}S] Met-tRNA into ternary complex (pmol)
Without kinase	
Complete (control I)	23.7
Complete + 65K ribosomal protein (1 μg)	22.5
Complete + 65K ribosomal protein (5 μg)	21.3
With kinase	
Complete (control II)	21.8
Complete + 65K ribosomal protein (5 μg)	12.0
Complete + 65K ribosomal protein (5 μg) + dsRNA (100 ng ml^{-1})	6.3
Complete + 65K ribosomal protein (5 μg) + aminopurine (2 mM)	16.7
Complete + dsRNA (100 ng ml^{-1})	19.7
Complete + aminopurine (2 mM)	20.0

The complete reaction mixture (0.1 ml) contained 20 mM Tris-HCl (*p*H 7.5), 4 mM dithiothreitol, 1 mM $MgCl_2$, 10 μg BSA, 0.1 mM ATP and 5 μg (bound with 23.7 pmol of [^{35}S]Met-tRNA$_f$) of purified eIF-2 (98% pure). The indicated concentrations of the reagent and eIF-2 (5 μg) were incubated for 10 min at 37 °C with 65K ribosomal protein (5 μg) in the presence or absence of IFN-induced kinase (0.5 μg). After incubation, the mixture containing 50 pmol of [^{35}S]Met-tRNA$_f$ (4,500 c.p.m. pmol^{-1}), 0.1 M KCl and 0.1 mM GTP was added to the reaction mixture and then further incubated for 10 min at 0–5 °C. The formed ternary complex of eIF-2 was determined as previously reported[2]. The eIF-2 from ribosomes of mouse L cells and IFN-induced kinase from ribosomes of mouse L cells treated with IFN (500 units for 24 h at 37 °C) were prepared as previously reported[2].

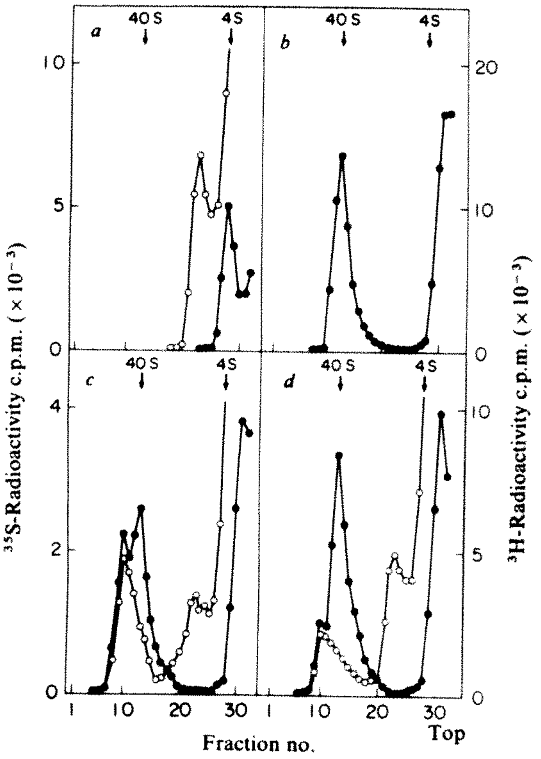

Fig. 2 Effect of 65K ribosomal protein on the binding of the ternary complex to the 40S ribosomal subunit. The reaction mixture (0.1 ml) contained 20 mM Tris-HCl (*p*H 7.5), 0.1 M KCl, 0.1 mM GTP, 50 pmol of [^{35}S]Met-tRNA$_f$ (4,500 c.p.m. pmol^{-1}), 10 pmol of [^{3}H] 40S subunit (0.16 A_{260} units), 1mM $MgCl_2$ and purified eIF-2 (5 μg). Incubation was for 10 min at 37 °C. The reaction mixtures were analysed 5–30% (w/v) sucrose density gradient (4.8 ml) in 20 mM Tris-HCl (*p*H 7.5), 0.1 M KCl and 1 mM $MgCl_2$. Centrifugation was at 45,000 r.p.m. in a Hitachi 50 SW rotor for 3 h at 4 °C. The gradients were divided separately into 10-drop fractions from the bottom of the tube. Radioactivities of ^{3}H and ^{35}S of the fractions were determined in a liquid scintillation spectrometer. *a*, ^{35}S radioactivity of the formed ternary complex ^{35}S-Met-tRNA$_f$–eIF-2–GTP, and ^{3}H-Met-tRNA$_f$ (1,300 c.p.m. pmol^{-1}, 30 pmol) after gel filtration of Sephadex G-25 to remove free ^{3}H-methionine; *b*, ^{3}H radioactivity of ^{3}H-40S subunit; *c*, the binding of the ternary complex to the ^{3}H-40S subunit (10 pmol). A ternary complex was formed in the condition as previously reported[1]. The binding assay was carried out in the presence of 65K ribosomal protein (5 μg) without IFN-induced kinase. *d*, Purified eIF-2 (98% pure, 5 μg) and 65K ribosomal protein (5 μg) were preincubated with the kinase (0.5 μg) in the presence of ATP (0.1 mM). After incubation (10 min at 37 °C), the reaction mixture was added to the binding assay mixture and then incubated for 5 min at 37 °C. ●, ^{3}H; ○, ^{35}S.

An interferon-induced cellular enzyme is incorporated into virions

David Wallach & Michel Revel

Department of Virology, The Weizmann Institute of Science, Rehovot, Israel

The mechanisms by which interferon inhibits viral growth are only partially understood. Several enzymatic activities increase in cells shortly after treatment with interferon[1–8]. One of these enzymes, oligo-isoadenylate synthetase, synthesizes (2′–5′) isoadenylate oligomers which strongly stimulate the activity of a cellular ribonuclease, RNase F (ref. 7). Interferon also significantly increases the activity of a protein kinase which phosphorylates the initiation factor eIF-2 and can inhibit *in vitro* protein synthesis. Such interferon-induced enzymes, which affect RNA and protein metabolism, might be responsible for many of its effects on viruses. Indeed, inhibition of viral protein and RNA synthesis appears to have a major role in the antiviral state[9]. We have now investigated possible interactions of the two enzymes with viral constituents during the course of infection and found that in two different membrane-coated RNA viruses, vesicular stomatitis virus (VSV) and Moloney murine leukaemia virus (M-MuLV), there is an accumulation of the (2′–5′) oligo-isoadenylate synthetase (E) in the virions. Most of the enzyme is bound to the virion ribonucleoprotein core. The incorporation of E into the virions suggests a direct involvement of the enzyme in regulation of virus functions.

Highly-purified VSV and M-MuLV virions were lysed in NP40, and after mixing with poly(rI):poly(rC)-agarose beads were incubated with [α-^{32}P]ATP. Figure 1 shows the autoradiography of an electrophoretic analysis of the labelled nucleotides formed with VSV virions, grown in BSC-1 monkey fibroblasts and with M-MuLV virions, from chronically infected NIH/3T3 mouse fibroblasts. The nucleotides formed during incubation of ATP with the respective cell extracts are shown in comparison. Equal amounts of proteins were used in the assay of the virions and of the cellular extracts. Before electrophoresis the labelled nucleotides were treated with bacterial alkaline phosphatase so that we analysed the phosphatase-resistant cores of the nucleotides formed by E comprising (2′–5′)ApA; (2′–5′)A(pA)$_2$ and so on.

Figure 1 (lanes 3, 4) shows that purified VSV virions, formed in BSC-1 cells, exhibit a high activity of E. The activity in the virions was proportional to that in the cells. BSC-1 cells which have not been treated with interferon showed low activity of E (Fig. 1, lane 1). Extracts of virions obtained from these untreated cell cultures also formed very little oligo-isoadenylate, but on a protein basis, the activity of E in the virions was about ninefold higher than in the cells (Fig. 1, lane 3). Treatment by 15 U per ml of interferon increased the activity of the enzyme in the cells and in the virions by about 10-fold (Fig. 1, lanes 2, 4). M-MuLV virions, and their host cells (NIH/3T3) showed no activity of E before treatment with interferon (Fig. 1, lanes 5, 7). Following treatment with interferon there was high activity of E in both the cells and the virions (Fig. 1, lanes 6, 8). The length of the oligo-isoadenylate formed by E is proportional to the activity of the enzyme. Thus, only the shortest oligomer, (2′–5′)ApA, is formed in the presence of low concentrations of lysed VSV virions (Fig. 1), while in the presence of higher concentrations of virion lysates there is also formation of (2′–5′)ApApA (Fig. 2*b*, lane 2). Further characterization of the nucleotides formed by VSV virions, is shown in Fig. 2. The products not treated with phosphatase were fractionated on a DEAE-cellulose column, in urea, from which, as shown before[7], dimer and trimer oligo-isoadenylates (2′–5′)pppApA and pppApApA elute sequentially as distinct peaks after the ATP (Fig. 2*a*, peaks I, II). In high voltage paper electrophoresis at *p*H 3.5 the nucleotides of peaks I and II migrated ahead of ADP, as the authentic oligo-isoadenylates[4,7] (not shown). Following treatment by phosphatase, the phosphatase-resistant cores co-migrated in the paper electrophoresis with (2′–5′) oligo A dimer and trimer markers and were clearly distinguished from (3′–5′) oligo A markers and from 5′-AMP (Fig. 2*b*, lanes 3, 4).

Table 1 Fractionation of NP40-treated VSV virions

	E activity (c.p.m. in (2′–5′)ApA)		Protein composition (% of total protein in the fraction)			
	No NP40	+NP40	L	G	N+NS	M
Intact virions	200	2400	2	22	39	35
NP-40 extract	—	230	<1	36	<1	57
NP-40 insoluble cores	1600	1600	3	6	67	25

Purified VSV virions (200 µg protein), labelled *in vivo* by ^{3}H-uridine, were suspended in 100 µl of 0.2% (v/v) NP40, 120 mM KCl, 5 mM MgCl$_2$, 7.5 mM β-mercaptoethanol and 10 mM HEPES buffer, *p*H 7.5. After incubation for 20 min at 4 °C they were applied on a 4-ml cushion of the same solution, but without NP40 and with 20% (w/v) sucrose, and spun for 60 min at 200,000 *g*. The proteins which did not sediment through the cushion were collected and the pelleted ribonucleoprotein cores were resuspended to the original volume of the virion sample in the above solution. Samples (5 µl) of the virions, of virion without NP40, of the non-sedimented proteins and of the NP40-insoluble proteins were assayed for E in the presence of poly(rI):poly(rC)-agarose as described in Fig. 1. The patterns of proteins in the virions and in the two fractions of the detergent-treated virus were analysed by SDS-electrophoresis on 7–18% gradient polyacrylamide gel and quantitated by densitometry. Quantification of the uridine label confirmed that at least 90% of the viral RNA was recovered in the NP40-insoluble pellet.

Although we used no direct visualization technique to confirm the localization of E in the virions, the following arguments eliminate the possibility that the virion activity results from contamination by cellular proteins. As shown in Fig. 1, lane 9, the M-MuLV virions showed very little activity of E unless they were disrupted by detergent. The activity of VSV showed a similar dependence on detergent treatment (Table 1). The enzyme is, therefore, found inside the virion and not just adsorbed on its surface. It is also very unlikely that the enzyme is found inside some cellular sub-particle which would co-purify with the virions, since the density at which VSV virions band is significantly different from the density of M-MuLV. Finally, as shown in Fig. 3, the activity of E fully coincides with the virion peak on sucrose gradient. Three successive sedimentation bandings of purified VSV virions in 20–30% sucrose gradients (between each the virions were dispersed by sonication) did not change the specific activity of E in the virions.

To examine the nature of the association between E and the virus we disrupted VSV virions by NP40 and separated the solubilized proteins from the RNA and its associated proteins (Table 1). The NP40-soluble fraction contained only the membrane-associated G protein and the M protein. Only little E activity was found in this fraction. The majority of the activity of E, originally found in the virions, was recovered in the detergent-resistant fraction (Table 1). This activity, in contrast to the activity of E in the intact virions, was not dependent on the addition of detergent. The detergent-resistant fraction contained all of the RNA-associated proteins L, N and NS, but significantly decreased amounts of the M proteins and very little G protein. Further fractionation of the NP40-insoluble core is necessary to identify the site at which E is bound; E has been shown to bind to double-stranded RNA and its activity is strongly stimulated by double-stranded RNA[6,10]. It seems unlikely that, in the virion, the enzyme is bound to a double-stranded portion of the RNA since the enzyme present in the virion was not active without the addition of the synthetic double-stranded RNA poly(rI):poly(rC). Full activation occurred at concentrations of 1–10 µg ml^{-1} poly(rI):poly(rC) (not shown). Preliminary results suggest that there is a difference between the affinity of virion-associated E and of cellular E for double-stranded RNA. At 0.12 M KCl, E from VSV virion

0028–0836/80/360068—03$01.00

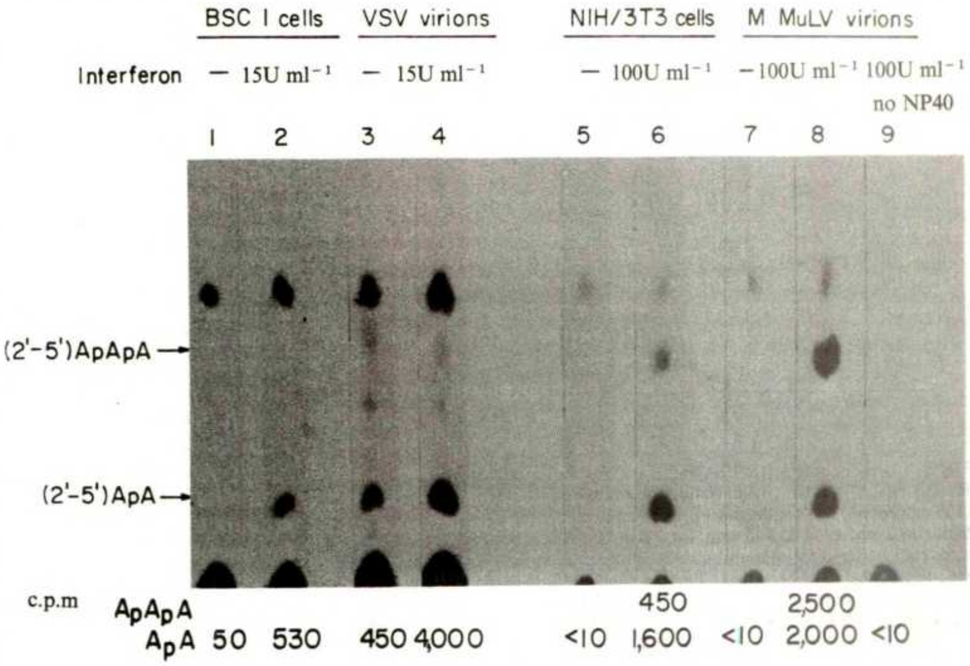

Fig. 1 Electrophoretic pattern of ATP-derived nucleotides formed by disrupted virions and by extracts of the infected cells. VSV (Indiana type, thrice plaque-purified) was collected 12 h after infecting BSC-1 cells with 0.02 plaque forming units (PFU) per cell. Following sedimentation of cell debris at low speed, the virus was sedimented through a cushion of 20% (w/v) sucrose in Dulbecco's phosphate-buffered saline (PBS) and then purified by velocity sedimentation banding in a 20–35% (w/v) sucrose gradient in PBS plus 2 mM EDTA followed by banding in a 20–40% (w/v) tartrate, 20%–0% (w/w) glycerol gradient in 20 mM Tris; 0.5 mM EDTA *p*H 7.4. Following each step the virus was dispersed by brief sonication. The virions formed a single sharp band on the gradients. M-MuLV, released by chronically infected NIH/3T3 cells[18] during a 24-h period, was purified by passing the cell-growth medium through a 0.45 μm Millipore filter, sedimenting the virus on a cushion of 60% sucrose and then banding in a 20–60% (w/v) sucrose gradient which also contained 10 mM Tris–HCl *p*H 7.4, 1 mM EDTA and 100 mM NaCl. Interferon was added to BSC-1 cells 24 h before the infection (15 U ml^{-1} human leukocyte interferon induced by Sendai virus in Namalva lymphoblastoid cells). NIH/3T3 cells were treated with 100 U ml^{-1} mouse interferon (induced by NDV in L929 fibroblasts) and 12 h later the medium was changed and interferon was re-added. Virions were collected 24 h after medium change. Both interferons were purified to about 10^7 U per mg protein. The purified virions were incubated for 20 h at 30 °C, with poly(rI):poly(rC)-agarose beads (PL Biochemicals) in the presence of 0.1% NP40 (except for lane 9), 1.25 mM [α-^{32}P]ATP (100–300 mCi mmol^{-1}), 5 mM magnesium acetate, 120 mM KCl, 1 mM dithiothreitol (DTT), 20 mM HEPES buffer, *p*H 7.5 and 10% glycerol. Following incubation, samples of the labelled products were treated by bacterial alkaline phosphatase and analysed by high-voltage paper electrophoresis at *p*H 3.5 using (2′–5′)ApA and (2′–5′)ApApA markers. E activity in cells was determined in the same conditions using NP40 extracts of cells prepared and pre-adsorbed on poly(rI):poly(rC)–agarose beads as described previously[6]. Equal amounts of viral and cellular proteins were applied on the beads (3 μg VSV and BSC-1 monkey cell proteins and 10 μg of M-MuLV and of chronically infected NIH/3T3 cell proteins). The labelled spots revealed in the autoradiogram given here, were cut out and counted with toluene scintillation fluid. The counts in the (2′–5′)ApA and (2′–5′)ApApA spots are given at the bottom of the figure. A background of 30 c.p.m. was subtracted.

lysates was readily eluted from poly(rI):poly(rC)-agarose beads. In the same conditions the enzyme of the BSC-1 cell extract remained adsorbed to the double-stranded RNA (not shown). The reason for the different behaviour of the virion-associated enzyme is not clear; it raises however the possibility that the interaction of E with viral components interferes with its binding to poly(rI):poly(rC). The mere fact that E is efficiently incorporated into the virions is also suggestive of some association between the enzyme and viral components. Without such an association it is difficult to see how E can be incorporated into

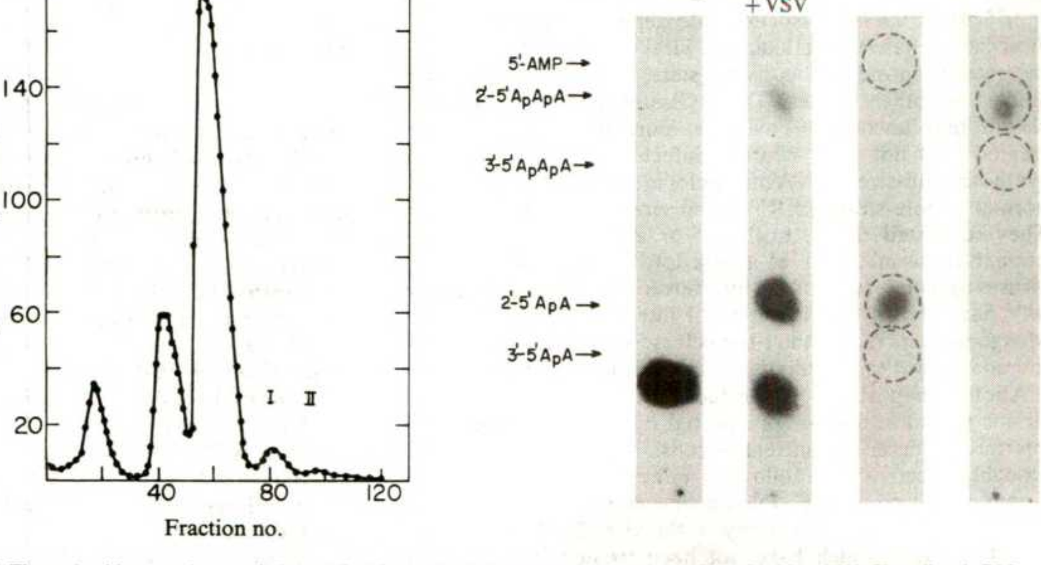

Fig. 2 Characterization of the oligo-isoadenylate synthesized by the disrupted virions. *a*, Chromatography on DEAE-Sephacel, of the nucleotides formed in incubation of lysed virions with [α-^{32}P]ATP. *b*, Electrophoretic analysis, following phosphatase treatment, of the nucleotides formed during the incubation with the virions (lane 2) and of fractions I and II (lanes 3, 4) from the DEAE-Sephacel chromatography. Unlabelled nucleotides, detected by UV light, are indicated by dotted lines [5′-AMP (2′–5′)ApA and (3′–5′)ApA in lane 3 and (2′–5′)ApApA and (3′–5′)ApApA in lane 4]. Lane 1 shows that the slowest migration spot is a contaminant of the [α-^{32}P]ATP preparation. A sample of purified VSV virions (80 μg protein) was incubated with: 100 μg ml^{-1} poly(rI):poly(rC); 1.25 mM [^{32}P]-α-ATP, 5 mM $MgCl_2$; 7 mM DDT, 20 mM HEPES, *p*H 7.5; 50 mM KCl; 10% glycerol and 0.1% NP40 in a final volume of 40 μl for 24 h at 30 °C. The nucleotides were then applied on a 0.7 × 16 cm DEAE-Sephacel column and eluted by a 50–250 mM NaCl gradient in 7 M urea and 50 mM Tris–HCl, *p*H 7.5 buffer. Fractions of 0.5 ml were collected and counted, without scintillation, in the ^{3}H-channel of a scintillation counter (*a*). The fractions in peak I and II were pooled, de-salted and concentrated by adsorption on a small DEAE-Sephacel column and then eluted by 1 M NH_4HCO_3. The nucleotides were treated by bacterial alkaline phosphatase and analysed by high-voltage paper electrophoresis as before[4] (*b*).

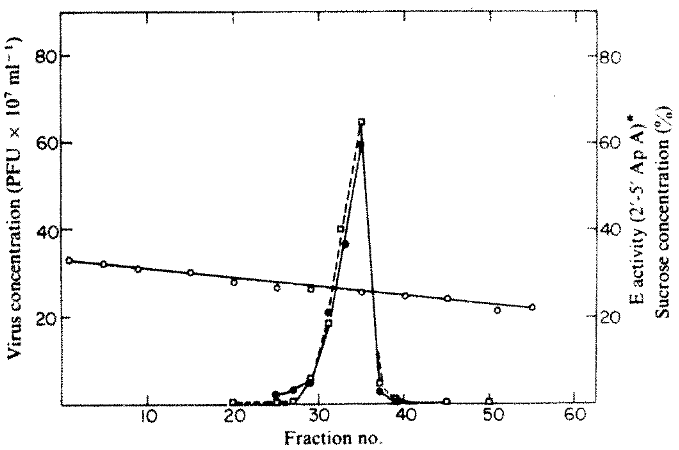

Fig. 3 Co-sedimentation of VSV and E activity. ●, Virus concentration; □, E activity; ○, sucrose concentration. A sample of purified VSV virions (100 μg protein) was applied on a sucrose gradient (13 ml 35%-20% w/v in PBS and 2 mM EDTA) and spun for 1 h at 100,000 *g*. Fractions of 0.3 ml were collected and the amount of virus in each fraction was determined by plaque assay on L929 fibroblasts. Sucrose concentration in the fractions was determined by refractometry. A sample of each fraction was diluted in PBS and spun again for 2 h at 250,000*g*. The pelleted virus was then resuspended in 40 μl of a solution of 120 mM KCl, 5 mM magnesium acetate, 1 mM DTT, 10% glycerol and 20 mM HEPES buffer, *p*H 7.5 and incubated for 18 h at 30 °C with 2.5 mM [α-^{32}P]ATP, 100 μg ml^{-1} poly(rI):poly(rC) and 0.1% NP40. Following phosphatase treatment, a sample was analysed by high-voltage electrophoresis followed by an autoradiography and spectrophotometric scanning of the (2'-5')ApA spots. E activity is expressed as the weight (in mg) of the paper under each scanning peak.

the virions to give activity which exceeds that in the cell, while most other cellular proteins are efficiently excluded from the virions in their assembly.

An interesting implication of the fact that E binds to viral components is that in virus-infected, interferon-treated cells, E is not likely to be evenly distributed but rather to be accumulated in subcellular sites in which there is assembly and synthesis of those viral components to which E can bind. Such uneven distribution of E in the cell might be an important factor in the function of this enzyme, and may result in a stronger effect of E on viral functions. It can also limit the effects of E on the cellular functions since degradation of the oligo-isoadenylate by the 2'-phosphodiesterase[7] might limit their effects [that is, activation of RNase F (ref. 7)] to the site of their synthesis in the cell. As has been pointed out by others, the strong stimulation of E activity by double-stranded RNA, formed during RNA replication of many viruses, might be an important factor in the specificity of the oligo-isoadenylate dependent ribonuclease[11]. Association between cellular and viral components, as part of the interferon-induced antiviral state, was also suggested in studies on other viruses. Thus, Glaster and Lengyel[12] have shown that uncoated reoviruses, purified from interferon-treated (but not from control) infected cells are unable to synthesize full-size mRNA molecules in spite of their apparently normal double-stranded RNA and viral protein composition. They suggested that a nuclease, or a factor which induces premature termination of transcription associates with the viruses upon infection of the interferon-treated cells. Aujean *et al.*[13] have shown that infection of interferon-treated cells by Mengo virus increased the ribonuclease activity in a subcellular fraction known to contain the viral replication complex.

Another implication of the fact that E accumulates in the virions is that E can be transported by the virion itself from interferon-treated to untreated cells. Inside the virion, E is probably inactive but, following infection and uncoating of virions which contain E, the enzyme might synthesize oligo-isoadenylate in close proximity to the viral RNA. Since cells, including those which have not been treated by interferon, contain RNase F which is activated by very low concentrations of oligo-isoadenylate[7], uncoating of the virus which contains E may eventually lead to its own destruction. Virions of MuLVs, formed by interferon-treated cells, have indeed been shown to have reduced infectivity[14,15]. It is possible that the defectiveness of these virions is not due to the alteration of a viral product[16,17], but rather to the incorporation into the virion of an interferon-induced cellular protein which interferes with the normal function of the virus.

So far, the study of the proteins induced by interferon concerned mainly their enzymatic activities. The presence of high amounts of E in virions suggests that besides their activity, the subcellular localization of these proteins and the mode of their interaction with the viral components can be of major importance in determining the way by which they protect cells against viruses.

We thank Mrs Ruth Yaniv for technical assistance, Mr Azriel Schmidt and Dr Edward Simon for helpful discussion, Dr Samuel Salzberg for the NIH/3T3 cells, Mr Gilles Merlin for human leukocyte interferon and Mr Lester Shulman for mouse interferon. This work was supported by GSF (München, FRG) and NCRD (Israel).

Identification of the lethal target of benzylpenicillin in *Streptococcus faecalis* by *in vivo* penicillin binding studies

R. Fontana*, P. Canepari†, G. Satta† & J. Coyette‡

The mode of bacterial killing by penicillins is still unknown in spite of many studies on the subject. The recent finding of multiple penicillin binding proteins (PBPs) in sensitive bacteria and the possibility of analysing the binding of the antibiotic to exponentially growing cells have provided new directions for investigating this problem[1-3]. Sensitivity to lethal and other effects of penicillin varies very significantly with the conditions of growth of the cells. If PBPs were the penicillin target, changes in conditions of growth causing variations in penicillin sensitivity should be accompanied by changes in these proteins. Furthermore, if one of PBPs could be identified as the killing target, it could possibly be demonstrated to show changes in cells growing in different conditions. We show here that in *Streptococcus faecalis* ATCC 9790 changes in conditions of growth are accompanied by changes in PBPs. Furthermore, in the presence of the minimal dose of ^{14}C-benzylpenicillin causing complete inhibition of cell growth, 100% of the total radioactivity is bound to a single protein (PBP 3).

To study the effect of benzylpenicillin on cells growing in different conditions, we have incubated the cells in the chemically defined medium (CDM) described by Shockman[4] at the

0028-0836/80/360070—03$01.00

temperature optimal for growth (45 °C, generation time 31.5 min) and at a temperature allowing a 1.5-fold lower growth rate (32 °C, generation time 47.27 min).

At 32 and 45 °C, the minimal doses of benzylpenicillin which inhibited cell growth (MIC) were 4 and 0.04 μg ml^{-1}, respectively, thus confirming the apparent direct dependence of penicillin sensitivity of *S. faecalis* cells on the growth rate.

Membranes from cells growing exponentially at 32 and 45 °C were treated with ^{14}C-benzylpenicillin and PBPs detected by polyacrylamide gel electrophoresis and fluorography as described in Fig. 1 legend. As Fig. 1 and Table 1 show, for most of the proteins, the proportion of the total radioactivity bound by the same protein at the two temperatures is clearly different. Note that the various PBPs respond in different ways to the changes of temperature: PBPs 1, 2 and 3 are present in a larger relative amount in membranes from cells grown at 45 than at 32 °C, whereas an increase in the relative amount of PBP 6 is found at the latter compared with the former temperature. This indicates that the changes in PBPs are not due to a nonspecific effect of temperature on these proteins. This was confirmed by the fact that, regardless of growth temperature, binding of penicillin was unaffected by the temperature (32, 37 or 45 °C) used during the binding assay (data not shown). Finally, PBPs of membranes from cells grown at 32 °C in streptococcal broth (SB)[5], a condition allowing a generation time of 35 min, appeared grossly different from those observed in membranes from cells grown at the same temperature in CDM and rather similar to those from cells grown in CDM at 45 °C (Fig. 1). Thus, two different conditions (temperature of incubation and growth medium) associated with changes in growth rate of the cells are also accompanied by changes in the physiological status of PBPs.

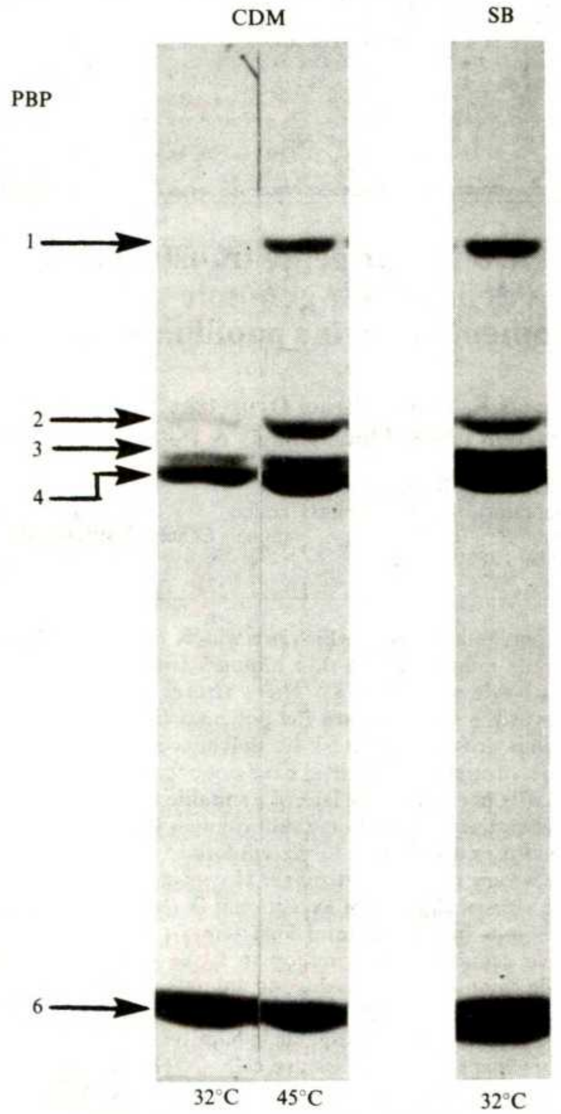

Fig. 1 Penicillin binding proteins of *S. faecalis* grown in different conditions. Membranes were prepared from cells exponentially growing in CDM (chemically defined medium) and in SB (streptococcal broth) and treated with 20 μM ^{14}C-benzylpenicillin (58 Ci mol^{-1}) at 37 °C for 15 min as described in ref. 5. The proteins were then fractionated by SDS-polyacrylamide gel electrophoresis[13] and the PBPs detected by fluorography[14]. PBP 5 has not been detected on these gels; this protein, like the PBPs 7 and 8 of *E. coli*[2], is not consistently observed.

Table 1 Per cent of radioactivity bound to PBPs in *S. faecalis* grown at 32 and 45 °C in CDM

		Per cent of radioactivity bound to				
		PBP 1	PBP 2	PBP 3	PBP 4	PBP 6
Isolated membranes	*A*	1.5	2.7	3.4	24.9	67.2
	B	8.7	11.4	15.7	26.6	37.4
Whole cells	*A*	1.7	1.4	14.2	21.1	57.3
	B	12.4	5.5	25.6	31.3	24.9

The amount of radioactivity bound to PBPs was determined by scanning the fluorograms shown in Figs 1 and 2*Af* and *Bf* with a Joyce-Loebl microdensitometer and calculating the area of the peaks thus obtained. The amount of radioactivity bound to each PBP is expressed as per cent of the total radioactivity bound. *A*, Cells grown at 32 °C; *B*, cells grown at 45 °C.

Cells growing exponentially at 32 and 45 °C were then treated with different concentrations of ^{14}C-benzylpenicillin and PBPs detected by polyacrylamide gel electrophoresis and fluorography. It is evident from Fig. 2 that the relative amount of radioactivity bound to the various PBPs of cells growing at different rates is also different when tested by *in vivo* binding experiments. Note that the differences observed in these conditions, although not similar for all proteins (compare PBPs 1 and 3), were most often of the same type as seen in isolated membranes (see Table 1). The differences between membranes and whole cells could be due to the different accessibility of some PBPs in whole cells and isolated membranes. Alternatively, they could depend on the incomplete saturation of PBPs in whole cells.

Concerning identification of the PBP that could be the lethal target of penicillin, Fig. 2 shows that only PBP 3 binds the antibiotic in cells growing at 45 °C in the presence of 0.04 μg ml^{-1} of ^{14}C-benzylpenicillin, a concentration corresponding to the MIC. In cells growing at 32°C and in the presence of the above concentration of antibiotic, PBP 3 was again the only protein that bound radioactivity. However, in these cells, the radioactivity bound to PBP 3 was approximately fourfold lower

Table 2 Evaluation of the absolute amount of radioactivity bound to PBPs in cells growing in the presence of various ^{14}C-benzylpenicillin concentrations

^{14}C-benzyl-penicillin concentration (μg ml^{-1})		Area of the peak (mm^2) corresponding to				
		PBP 1	PBP 2	PBP 3	PBP 4	PBP 6
0.02	*A*	—	—	43	—	—
	B	—	—	100	—	—
0.04	*A*	—	—	53	—	—
	B	—	—	228	—	—
0.08	*A*	—	11	82	—	—
	B	48	40	252	—	—
0.32	*A*	6	15	112	32	54
	B	72	48	274	—	21
0.80	*A*	32	18	189	297	580
	B	105	57	280	324	63
4.00	*A*	25	20	200	352	804
	B	161	72	332	406	322

The intensities of the bands were measured by scanning the fluorograms shown in Fig. 2*A* and *B* and calculating the area of the peaks thus obtained. *A*, Cells growing at 32 °C; *B*, cells growing at 45 °C.

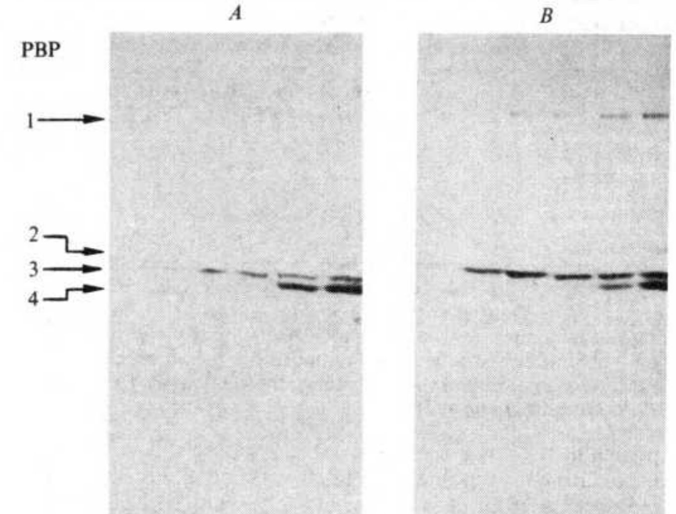

Fig. 2 Penicillin binding to membrane proteins in whole cells of *S. faecalis*. Samples (10 ml) of cells exponentially growing at 32 (A) or 45 °C (*B*) (2×10^8 bacteria per ml) were treated with doses of ^{14}C-benzylpenicillin ranging from 0.02 to 4 μg ml^{-1}. After 5 min, 10 mM cold penicillin was added, the cultures were rapidly chilled and membranes from cells were prepared as described previously[5] with the only exception that lysozyme digestion was carried out by incubating the cells for 30 min at the same temperature as used for growth. No significant breakdown of PBP–penicillin complexes occurred during the preparation of membranes, as only PBP 4 showed a 10% loss of the radioactive label after 30 min of incubation at either temperature (data not shown). Electrophoresis of radioactive membranes and detection of PBPs were carried out as described previously[13,14]. The following concentrations of ^{14}C-benzylpenicillin were used (μg ml^{-1}): *a*, 0.02; *b*, 0.04; *c*, 0.08; *d*, 0.32; *e*, 0.8; *f*, 4.

than that bound in cells growing at 45 °C in the same conditions (Table 2). In the presence of the minimal concentration of benzylpenicillin causing inhibition of cell growth at 32 °C, all PBPs bound radioactivity and the amount of ^{14}C-benzylpenicillin bound by PBP 3 was very close to that bound in the presence of the MIC at 45 °C (Fig. 2, Table 2).

The data presented here clearly indicate that growth of cells incubated at 45 °C could be inhibited through specific binding of penicillin to PBP 3. This protein seems to be the lethal target in *S. faecalis* and sensitivity to the antibiotic seems to depend on the capability of penicillin to bind it. Furthermore, (1) penicillin binds only to PBP 3 in cells growing at 45 °C in the presence of the MIC of the antibiotic; (2) in cells which require a much higher dose of antibiotic for inhibition, a much reduced amount of radioactivity is bound to PBP 3; (3) in the presence of the respective MIC of penicillin at both 32 and 45 °C, the same amount of radioactivity is bound to PBP 3. This could suggest that a minimal dose of penicillin is required to bring about interference with the vital function of PBP 3. Spratt has recently described a mutant of *Escherichia coli* in which resistance to mecillinam is due to the reduced capability of PBP 2 to bind the antibiotic[2]. Similarly, the reduced sensitivity to penicillin of *S. faecalis* observed at 32 °C could be due to the reduced amount of penicillin bound by PBP 3.

Alternatively, the reduced sensitivity observed at 32 °C could be due to the fact that PBP 3 cannot be the lethal target in cells growing in these conditions. This possibility is supported by the fact that the amount of penicillin bound to other PBPs also changes in these conditions. PBPs could perform their functions by interacting in a complex way so that the function of each one (or some of them) depends on the activity of other PBPs (see also ref. 6). In *S. faecalis*, PBP 3 could have an essential role in cell growth at 45 °C, but not at 32 °C, due to changes in the physiological status of this and other PBPs. This could explain different effects observed by various authors and the different mechanisms of bacterial killing proposed[7-12]. Penicillins could have the main property of binding to proteins and interfering with their functions. The effects of penicillins could then depend on the specific function of the bound proteins in a given system and in specific experimental conditions.

In vitro tumorigenic transformation by a defined sub-genomic fragment of bovine papilloma virus DNA

Douglas R. Lowy*, Israel Dvoretzky*, Ralph Shober†, Ming-Fan Law‡, Linda Engel‡ & Peter M. Howley‡

* Dermatology Branch,
† Laboratory of Tumor Virus Genetics,
‡ Laboratory of Pathology, National Cancer Institute, Bethesda, Maryland 20205

The papillomaviruses, which are widely distributed in nature, typically induce benign skin tumours (warts) in their natural hosts (reviewed in ref. 1). These viruses are members of the papovavirus group, as are the polyomaviruses[2]. In contrast to polyomaviruses such as SV40, polyoma and BK (reviewed in ref. 3), the papillomaviruses have not been extensively studied, primarily because of the lack of a suitable tissue culture system. In general, the proliferative skin changes induced by the papillomaviruses are limited to the epidermal cells, and the viruses have a very narrow host range. However, some bovine papilloma viruses (BPV) are exceptional in that they induce fibropapillomas in their natural host (cows); these BPV can also induce cellular transformation in tissue culture[4-6] and fibroblastic tumours in heterologous animals, including hamsters[7], mice[5] and horses[8,9]. BPV DNA from virions can also transform rodent cells and is tumorigenic in hamsters[10]. Recently, a tissue culture focus assay[11] in mouse cells (NIH 3T3 and C127) has been described for those BPV which are the aetiological agents of fibropapillomas in cows. The virally transformed cells, which did not contain infectious virus, grew in soft agar and were tumorigenic in nude (*nu*/*nu*) mice. We[12] have recently molecularly cloned the entire genomes of BPV-1 and BPV-2 (ref. 13) in *Escherichia coli* K12 using the certified plasmid vector pBR322 (ref. 14). We now demonstrate that these cloned DNAs can transform NIH 3T3 and C127 cells. Further, a molecularly cloned fragment which contains 69% of the BPV-1 genome can also induce cellular transformation.

A linear physical map of the 8-kilobase pair closed circular BPV-1 DNA genome (from papilloma 307) is shown at the top of Fig. 1. Restriction endonucleases *Hin*dIII, *Bam*HI, *Eco*RI and *Hpa*I each cleave the viral DNA once, at 0, 0.31, 0.60 and 0.88 map units, respectively[15]. The BPV DNA genome was cloned in pBR322 at the *Bam*HI site (clone 8-2) and also at the *Hin*dIII site (clone 9-1)[12]. After digestion with the enzyme used to insert BPV DNA into the pBR322 vector, the DNA was transfected[16] into C127 and NIH 3T3 mouse cells. Within 2 weeks, foci of transformed cells appeared in each cell line (Fig. 1, expt 1). These foci, which were more distinct on the C127 cells than in the NIH 3T3 cells, were indistinguishable morphologically from foci induced by BPV virions in the same cells. Transfection of NIH 3T3 cells resulted in two to three times more foci than observed in C127 cells with either BPV-1 cloned DNA; this greater sensitivity of the NIH 3T3 cells was also noted following infection with whole virions[10]. In each cell line the two different BPV-1 DNA preparations induced a similar number of foci. BPV-2 DNA, which shows extensive sequence homology with BPV-1 DNA, was cloned in pBR322 at its unique *Hin*dIII site; after digestion with *Hin*dIII, this cloned DNA also induced foci in this transfection experiment (data not shown).

Because BPV-1 DNA linearized at either the *Hin*dIII or *Bam*HI site was equally efficient in transforming these mouse cells, it seemed likely that some BPV-1 sequences might not be required for the induction of cellular transformation. We therefore examined the ability of defined sub-genomic fragments of the cloned viral DNAs to transform the mouse cells. The DNA fragments were prepared by digestion of the *Bam*HI BPV-1 DNA insert with a second restriction endonuclease which cleaved the BPV DNA at a unique site (*Hin*dIII, *Eco*RI and *Hpa*I). The BPV fragments were separated by agarose gel electrophoresis, individually eluted from the gel and transfected into the mouse cells. Of the various cleavage products tested, only the 69% *Bam*HI/*Hin*dIII fragment still induced foci, although its efficiency was lower than that of the complete BPV genome (expt 2). The other sub-genomic fragments tested failed to induce foci.

Table 1 Growth in agar and tumorigenicity of BPV DNA transformants

Transforming agent	Colony formation in agar	Tumour formation in nude mice
Control cells	0	0/4
BPV-1 virus	1.4×10^{3}*	4/4†
*Hin*dIII genome, focus 52	0.6×10^{3}	4/4
*Bam*HI genome, focus 33	2.2×10^{3}	4/4
*Bam*HI genome, focus 43	1.3×10^{3}	4/4
69% Fragment clone 17-6, focus 21	0.8×10^{3}	4/4
69% Fragment clone 17-6, focus 22	1.6×10^{3}	4/4
69% Fragment clone 17-2, focus 24	1.1×10^{3}	4/4
69% Fragment clone 17-2, focus 25	1.9×10^{3}	4/4

Each BPV DNA transformant was isolated from a different dish of C127 cells to ensure that each was separately derived. Each focus of transformed cells was picked 3 weeks after transfection of DNA and propagated separately. Colony formation in 0.35% agar was carried out as described elsewhere[18]. Weanling nude mice were inoculated subcutaneously with 10^6 transformed cells. Tumours were present in all animals by 3 weeks after inoculation. Control animals were observed for 8 weeks.

* No. of colonies per 10^4 cells.

† No. of mice with tumours/no. of mice inoculated with cells.

To eliminate the possibility that the infectivity of the 69% *Bam*HI/*Hin*dIII fragment might be due to the transfection of additional BPV DNA sequences contaminating this DNA in the agarose gel, this fragment and the 31% *Bam*HI/*Hin*dIII fragment were each subcloned in pBR322 from the *Bam*HI BPV clone. Two subclones of each fragment were tested in the C127 mouse cell transfection assay. After separating the BPV DNA from the pBR DNA by digestion with *Bam*HI/*Hin*dIII, both the 69% fragment clones induced foci but the 31% fragment clones failed to do so (expt 3). As noted previously, the specific infectivity of the 69% sub-genomic fragment was lower than that of the complete viral genome. Southern blot analysis of DNA from the transformed cells has indicated that, as expected, the transformants contained BPV DNA sequences from the 69% fragment and no sequences which hybridized with the 31% fragment (M.-F.L. *et al.*, unpublished data).

A good correlation has been noted[17] between anchorage-independent growth of transformed cells and their capacity to be tumorigenic in nude mice. The ability of the BPV-transformed

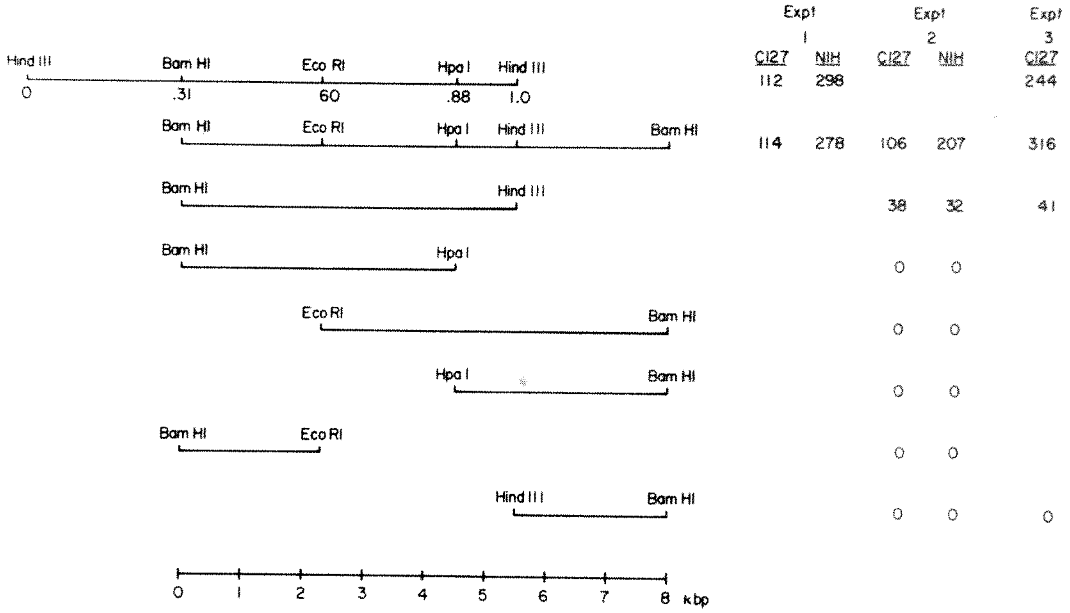

Fig. 1 Duplicate dishes were transfected with restriction endonuclease-digested DNA (0.1 to 0.5 μg per dish) using calf thymus DNA (25 μg ml^{-1}) as carrier[16,24] (similar results were obtained when NIH 3T3 DNA was used as carrier). Foci were counted at 2 weeks for C127 cells and 4 or 5 days later for NIH 3T3 cells. Results are expressed as focus forming units per μg BPV DNA. pBR322 controls were included with each experiment and did not induce foci. A zero means that no foci were observed after testing 1 μg of DNA. In expt 2, the *Bam*HI DNA insert from clone 8-2 was digested with each of the other three enzymes. The DNA was electrophoresed in a 1% agarose gel after restriction endonuclease digestion. The ethidium bromide-stained BPV DNA bands were cut out of the gel and transfected into the cells as previously described[24]. In expt 3, the 69% and 31% *Bam*HI/*Hin*dIII fragments used were clones 17-6 and 16-9, respectively. The DNAs were digested with *Hin*dIII/*Bam*HI, electrophoresed and transfected as in expt 2. kbp, Kilobase pairs.

cells to form colonies in agar[18] and to induce tumours in weanling nude mice has therefore been tested. Transformants derived from individual foci induced in C127 cells by the *Hin*dIII BPV genome, the *Bam*HI BPV genome and the 69% *Bam*HI/*Hin*dIII fragment all grew in soft agar; these cells also induced tumours in the mice after a latent period of 2–3 weeks (Table 1). Mice inoculated with control cells did not develop tumours during 8 weeks of observation.

These observations indicate that not all sequences of the BPV genome are required for cellular transformation. In this regard, the results are similar to those reported for other DNA tumour viruses, such as polyomaviruses and adenoviruses (reviewed in ref. 19). The sequences contained in the 31% *Bam*HI/*Hin*dIII fragment were not essential for the induction of transformation. It is likely that further study may reveal additional BPV sequences which are not required for transformation.

It is not clear why the transforming efficiency of the subgenomic fragment was lower than that of the entire viral genome. It is possible that some of the BPV sequences from 0–0.31 map units may have a specific facilitative role, as has been shown in transformation[20–22] by retroviruses. Alternatively, the smaller size of the fragment or the presence of non-homologous ends may introduce physical constraints which by themselves lower the efficiency of the transfection assay, if circularization of the viral DNA occurs. These or other possibilities may be evaluated by future studies.

The precise relevance of these *in vitro* results to *in vivo* tumours induced by BPV or other papillomaviruses remains to be established. From our data, it may be speculated that *in vivo* transformation of epidermal and fibroblastic cells by BPV does not depend on viral replication. This hypothesis is supported by the observation that the fibroblastic component of BPV-induced tumours does not contain detectable amounts of infectious virus[8]. Some data also suggest that the results obtained with BPV may be relevant to infection with other papillomaviruses. It has recently been demonstrated[23] that BPV DNA (types 1 and 2) contains nucleotide sequences which show homology with human papilloma virus type 1 and with Shope rabbit papilloma virus; this suggests that these viral genomes may be organized similarly. It may further be significant that one of these regions of homology is contained within the transforming 69% *Bam*HI/*Hin*dIII BPV-1 DNA fragment.

Calcium-dependent phosphorylation of histone H3 in butyrate-treated HeLa cells

James P. Whitlock Jr, Robert Augustine & Howard Schulman

Department of Pharmacology, Stanford University School of Medicine, Stanford, California 94305

Ca^{2+} is prominant in the control of cell proliferation and function[1,2]. However, the biochemical mechanism(s) mediating its effects on nuclear events is unknown. We report here that Ca^{2+}, at physiological concentrations, stimulates the phosphorylation of histone H3 by an endogenous protein kinase in HeLa cell nuclei. Also, pretreatment of cells with Na butyrate, which increases histone acetylation, selectively increases the susceptibility of histone H3 to phosphorylation by the protein kinase. Our results reveal a potential link between histone H3 acetylation and phosphorylation, modifications which are thought to have important effects on chromatin structure and function and suggest a possible mechanism whereby stimuli at the cell surface (such as hormones, mitogens and drugs) may influence biochemical events at the nuclear level; changes in the intracellular Ca^{2+} concentration may influence the phosphorylation of chromosomal proteins, mediated by Ca^{2+}-dependent kinases in the nucleus.

HeLa cells are known to contain a nuclear kinase(s) which phosphorylates histone H3 (ref. 3). We studied histone phosphorylation by incubating HeLa nuclei with [γ-^{32}P]ATP. The nuclei were then washed in 0.3 M NaCl to remove many of the non-histone nuclear proteins. The salt-washed nuclei were extracted with dilute HCl, and the acid-soluble proteins were precipitated and analysed by SDS–polyacrylamide gel electrophoresis and autoradiography. The autoradiogram shown in Fig. 1 indicates that radioactive phosphate is incorporated into an acid-soluble protein which has a mobility identical to that of histone H3. Additional experiments (not shown) indicate that this protein is not removed when nuclei are washed in 0.6 M NaCl but is removed when the NaCl concentration is raised to 2.0 M. Thus, the properties of this protein are identical to those of histone H3 (ref. 4).

Ca^{2+}, at submicromolar concentrations, causes a marked and selective stimulation of ^{32}P incorporation into histone H3 (Fig. 1). In these experiments, the free Ca^{2+} concentration was varied by using a Ca^{2+}-EGTA buffer containing 0.4 mM EGTA (ref. 5). Quantitative densitometry of the autoradiograms indicates that Ca^{2+}, at concentrations of 0.1 μM and 0.5 μM, increases the phosphorylation of histone H3 two- to threefold. Higher Ca^{2+} concentrations (up to 10 mM) produce no further increase in H3 phosphorylation (data not shown). Thus, the phosphorylation of histone H3 is stimulated by Ca^{2+} at concentrations which are presumably physiological. In analogous experiments, we observed that cyclic AMP (10 μM) and cyclic GMP (10 μM) had no effect on H3 phosphorylation (data not shown).

The amino acid residues in histone H3 which are known to undergo phosphorylation are located in the amino terminal region of the protein[6]; this is the same region which undergoes acetylation *in vivo*[6]. We therefore wondered whether one type of histone H3 modification (acetylation) influenced the susceptibility of the protein to a second type of modification (phosphorylation). Cells cultured in the presence of butyric acid accumulate hyperacetylated histones, due to the inhibition of histone deacetylation by butyrate[7–13]. In agreement with the observations of others, we find that exposure of HeLa cells to 5 mM Na butyrate for 16–24 h produces marked acetylation of histones, as judged by the distribution of acetylated forms of

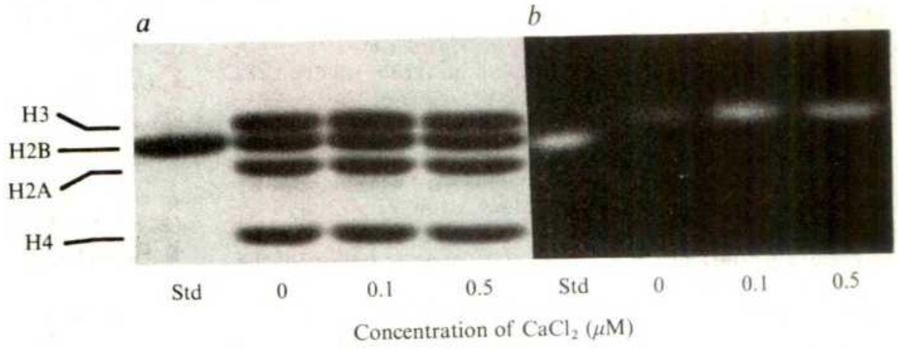

Fig. 1 Calcium-dependent phosphorylation of histone H3 in HeLa cells: *a*, stained gel; *b*, autoradiogram. HeLa cells were grown in monolayers to approximate confluence in Dulbecco's modified Eagle's medium (Gibco). Cells were washed twice with ice-cold phosphate-buffered saline (PBS), collected by scraping into PBS, and pelleted. Nuclei were prepared by Dounce homogenization in the presence of 1% Triton X-100 (ref. 21). Washed nuclei were suspended in a solution of 0.15 M NaCl, 5 mM MgCl$_2$, 5 mM dithiothreitol and 5 mM Na butyrate in 50 mM Tris–HCl, *p*H 7.5 containing the indicated concentration of free Ca^{2+}. The free Ca^{2+} concentration was calculated using an apparent binding constant for Ca^{2+}–EGTA of 7.61×10^6 M^{-1} (ref. 22). The reaction was started by the addition of [γ-^{32}P]ATP (Amersham; 10–50 Ci mmol^{-1}) to a final concentration of 1 μM. Nuclei were incubated at room temperature (22 °C) for 5 min. Preliminary experiments indicated that, under these conditions, the phosphorylation of histone H3 continues to completion. The phosphorylation reaction was stopped by the addition of EDTA to a final concentration of 10 mM. Nuclei were washed following the addition of NaCl to a final concentration of 0.3 M and the salt-washed nuclei were collected by centrifugation. The salt-washed nuclei were extracted for 1 h with ice-cold 0.25 M HCl and centrifuged to pellet the precipitate. The supernatant was removed and precipitated overnight at −20 °C by the addition of 10 volumes of acetone. The precipitate was collected by centrifugation, dissolved in sample buffer and analysed by electrophoresis in discontinuous SDS–polyacrylamide gels[23]. Purified calf thymus histone H2B (Boehringer-Mannheim) was phosphorylated *in vitro*, using [γ-^{32}P]ATP and a purified cyclic AMP-dependent protein kinase and was included in the analysis as a molecular weight standard. The gels were stained with Coomassie blue, destained, and subjected to autoradiography as previously described[23,24]. Electrophoresis was from top to bottom. The positions of the core histones are indicated. Std, H2B standard.

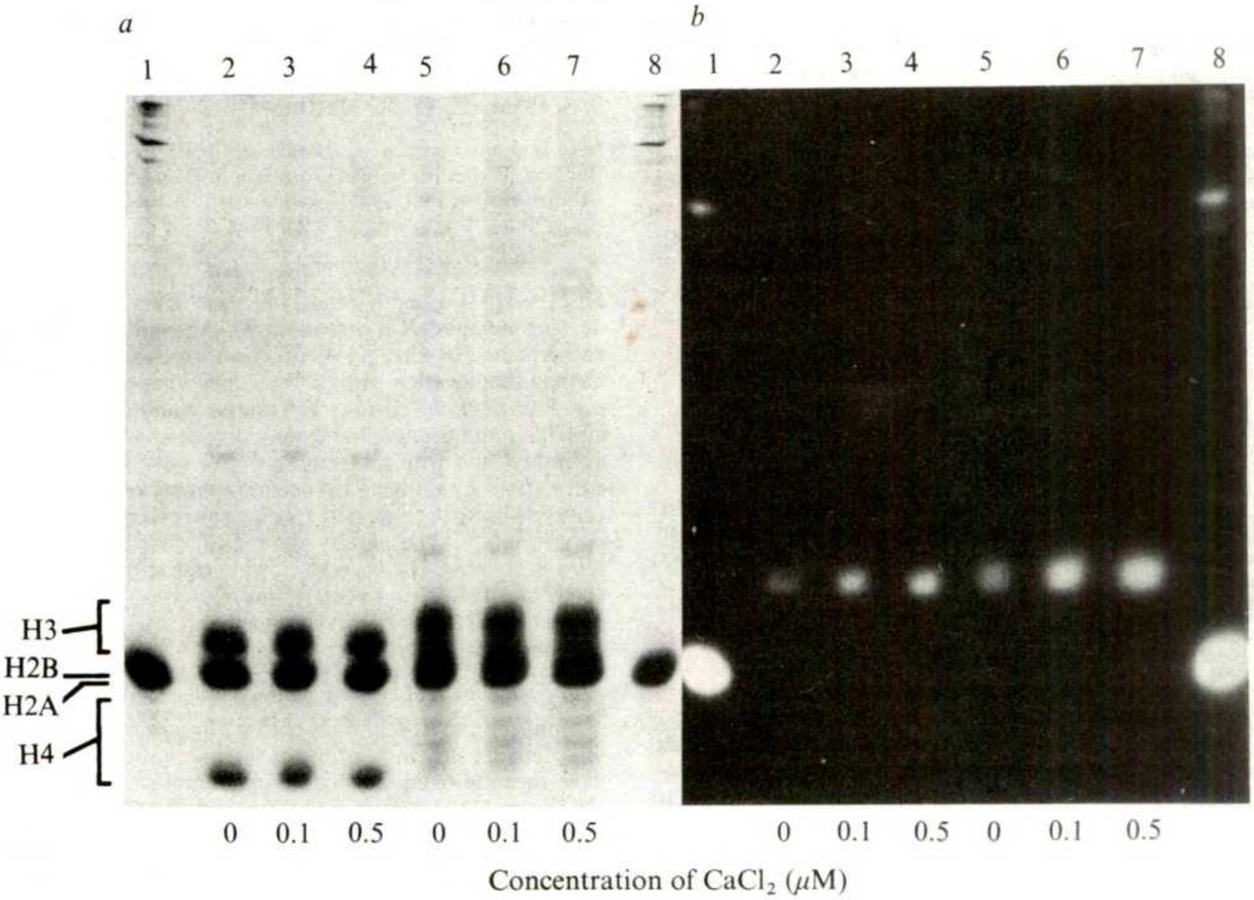

Fig. 2 Histone H3 phosphorylation in butyrate-treated HeLa cells: *a*, stained gel; *b*, autoradiogram. Cells were incubated for 16 h in the absence or presence of Na butyrate (5 mM). Cells were collected and nuclei were prepared as described in the legend to Fig. 1, except that, in the case of butyrate-treated cells, all solutions contained 5 mM Na butyrate. The phosphorylation reaction and isolation of acid-soluble proteins was as described in the legend to Fig. 1. The acetone precipitate was dissolved in sample buffer and analysed by electrophoresis in polyacrylamide gels containing acetic acid and urea[12]. Gels were stained in Coomassie blue, destained, and subjected to autoradiography as previously described[23,24]. Electrophoresis was from top to bottom. The positions of the core histones are indicated. Lanes 1 and 8, H2B standard; lanes 2–4, control (not butyrate-treated); lanes 5–7, butyrate-treated.

histone H4 after electrophoresis in polyacrylamide gels containing acetic acid and urea.

We prepared nuclei from control and butyrate-treated cells (5 mM, 16 h), incubated them in the presence of $[\gamma\text{-}^{32}\text{P}]$ATP, washed the nuclei in 0.3 M NaCl, extracted the nuclei with dilute HCl, and analysed the acid-soluble protein by electrophoresis in acetic acid–urea–polyacrylamide gels, followed by autoradiography. The results (Fig. 2) indicate that histone H3 in butyrate-treated cells is more susceptible to phosphorylation than is histone H3 from control cells. Quantitative densitometry of the autoradiogram indicates that two to three times as much phosphate is incorporated into histone H3 in butyrate-treated cells as is incorporated into histone H3 in control cells (data not shown). In both control and butyrate-treated cells, the phosphorylation of histone H3 is stimulated two- to threefold in the presence of submicromolar concentrations of Ca^{2+} (Fig. 2).

Several kinds of experiments suggest that it is acetylation, *per se*, which renders histone H3 more susceptible to phosphorylation: (1) dose–response experiments (exposure of cells to 0–50 mM Na butyrate for 16 h) and time-course experiments (5 mM Na butyrate for 0–24 h) demonstrate a correlation between increased acetylation and increased phosphorylation; (2) both the hyperacetylation and the increased susceptibility to phosphorylation are rapidly reversed following the removal of butyrate (5 mM) from the medium; (3) exchange experiments (such as incubating kinase-depleted nuclei prepared from butyrate-treated cells with protein kinase activity prepared from control nuclei and vice versa) indicate that the increased phosphorylation is due to an alteration in the histone substrate rather than to a change in the kinase (data not shown).

Our results suggest that an acetylated form(s) of histone H3 is particularly susceptible to phosphorylation and that this event is Ca^{2+}-dependent. The effect of Ca^{2+} presumably reflects a stimulation of protein kinase activity, although we cannot rule out the possibility that its primary effect is to alter the conformation of the histone substrate. The absence of a stained band with a mobility identical to that of the phosphorylated H3 species indicates that it is a relatively small subpopulation of H3 molecules which becomes phosphorylated (Fig. 2). The autoradiogram (Fig. 2) indicates that the phosphorylated form(s) of histone H3 migrates more slowly than the most highly acetylated form(s) of H3 visible on the stained gel. Our findings are consistent with the idea that, in both control and butyrate-treated cells, the most highly acetylated form(s) of H3 is most susceptible to phosphorylation.

In eukaryotic cells, the arginine-rich histones H3 and H4 seem to be of fundamental importance in the folding of nuclear DNA into the nucleoprotein complex known as chromatin[14-16]. The amino acid sequences of both H3 and H4 have been highly conserved throughout evolution[17]; therefore, it is argued that, in principle, chemical modification of a histone(s) could produce important changes in chromatin structure and function. In practice, there is considerable circumstantial evidence to support the view that both acetylation and phosphorylation of the histones have substantial structural and functional effects on the nucleoprotein[6,14,17-19].

Recently, there has been renewed appreciation of the importance of Ca^{2+} in regulating various cellular functions (such as the response to hormonal stimulation and the stimulus-coupled release of neurotransmitters or peptide hormones)[1,2]. It is becoming apparent that Ca^{2+}-dependent protein kinases may mediate some of the intracellular actions of Ca^{2+} and thereby play a central role in regulating the physiological responses of the cell to changes in its external environment[20]. Such Ca^{2+}-dependent kinases have been identified in both membrane and cytosol preparations. Our experiments indicate that such an enzyme(s) may also be present in the nucleus and can utilize a chromosomal protein as a substrate, suggesting a mechanism by which changes in intracellular Ca^{2+} may influence biochemical events in the cell nucleus.

† Department of Biological Chemistry, School of Medicine, University of California, Davis, California 95616

Histone H4 is a highly conserved structural component of the nucleosome subunit of chromatin. The activation of chromatin is accompanied by changes in structure which may be caused by histone modification or by interactions of specific non-histone proteins, or both. Histone H4 can be modified by acetylation and this modification has been correlated with chromosome assembly[1] and with transcription[2]. We have now tested these correlations by studying H4 acetate content as a function of the cell cycle using the naturally synchronous cell cycle in *Physarum polycephalum*. The results show two clear correlations: (1) tetra-acetylated H4 correlates with transcription; (2) highly acetylated H4 (2 to 4 acetates per molecule) is inversely correlated with H1 phosphorylation and initiation of chromosome condensation in prophase. The results are consistent with turnover of di-acetylated H4 during chromosome assembly in S phase.

Mohberg and Rusch[3] showed that *Physarum* has histones like other eukaryotes and the bands they identified as H1 and H4 have recently been isolated[4]. The amino acid composition of *Physarum* H4 shows no significant difference from the amino acid composition of calf thymus H4. *Physarum* H4 co-migrates with calf thymus H4 in polyacrylamide gel electrophoresis (PAGE) in acetic acid–urea or SDS or Triton X-100 (Fig. 1).

Physarum H4 splits into five bands on long polyacrylamide gels with acetic acid–urea or Triton X-100 but not with SDS. Only very small amounts of ^{32}P are incorporated into *Physarum* H4 in plasmodia[5]—certainly not enough to account for the observed heterogeneity. By analogy with other H4 histones the heterogeneity was attributed to acetylation and this was confirmed by pulse-labelling experiments and by enhancement

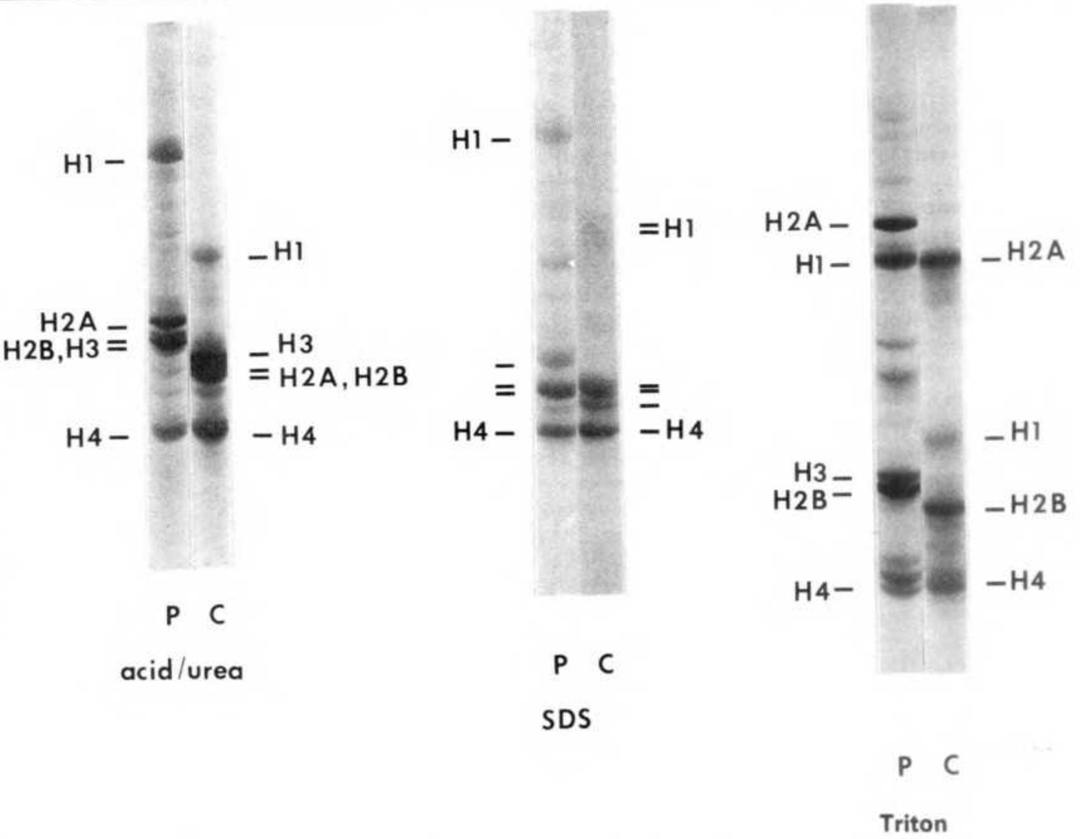

Fig. 1 Comparison of histones from *Physarum* plasmodia and calf thymus by acrylamide gel electrophoresis in the presence of SDS[35]; acetic acid and urea[8]; Triton X-100[36]. C, calf thymus; P, *Physarum*. The labelled bands were identified by electrophoresis of purified histone fractions. Electrophoresis was from top to bottom in 6-mm internal diameter glass tubes, 6 cm long. These gels are not long enough to resolve the H4 species adequately.

of the slower moving bands when butyrate[6] was added to the growth medium (Fig. 2*a*).

The proportion of *Physarum* H4 in each of the five bands was determined by PAGE in acetic acid–urea[7,8]. The H4 was first purified by chromatography on Biogel P10 to reduce the amount of protein loaded on the gels and to remove a minor component that interfered with the measurement of tetra-acetylated H4, Ac_4H4.

Figure 2*b* shows examples of gel scans of *Physarum* H4 from specific stages of the cell cycle. These and others have been analysed in terms of five gaussian peaks and the area under each peak calculated. The areas were thus fully corrected for the overlap between bands. The area corresponding to each species of H4 is plotted in Fig. 3*a* as a function of stage of the cell cycle.

It is clear that at all stages the most abundant species is mono-acetylated H4, Ac_1H4. During G2 phase the proportion of Ac_1H4 rises to ~62% and then falls to ~55%. The fall occurs during the middle part of G2, from 5 h to ~9 h after mitosis in the 11-h cycle. During the 6–9-h period after mitosis there are complementary increases in proportions of Ac_2H4 (16% to 23%), Ac_3H4 (2.5% to 4.3%) and Ac_4H4 (1% to 3%). The data imply an overall increase in acetylation during mid G2 phase. Late G2 is characterized by a sharp drop in Ac_4H4 (3% to 1%), followed in early prophase by a drop in Ac_3H4 (4% to 2%). Ac_2H4 drops sharply through late G2 and prophase (23% to 11%). In early prophase the overall proportion of highly acetylated H4 (2 to 4 acetates per moledule) is at its minimum value (13.5%). During late mitosis and early S phase the increase in proportion of highly acetylated H4 is balanced by drops in both non- and mono-acetylated H4 so that in mid S phase the proportion of highly acetylated H4 reaches its maximum (33.6%). In late S phase the proportion of highly acetylated H4 falls to a plateau level (about 26%) before the minimum (19.4%) in early G2 phase. The most dramatic changes in an individual H4 species occur in Ac_4H4 and these are shown on an expanded scale in Fig. 3*b*. There is a clear minimum (0.4%) in early prophase, a sharp maximum (3.6%) in mid S phase and a second maximum (up to 3%) in mid G2 phase.

Histone H4 is extensively modified in the cytoplasm before entry into the nucleus in duck erythroid cells[7] and in hepatoma cell culture[9]. Figure 3*a* shows a peak of Ac_2H4 in S phase nuclei that is consistent with the notion that newly synthesized H4 enters the nucleus in the di-acetyl form and is then converted to the unmodified form, which shows an increase in late S phase (M2 + 1 h to M2 + 2.5 h) following the increase in Ac_2H4 (M2 to M2 + 1 h). This suggestion is analogous to the situation in HTC cells[9] but pulse-label experiments are required to confirm this interpretation in *Physarum*.

Transcription in *Physarum* during the cell cycle is probably biphasic[10–13] with a very low level in mitosis, a high level in S phase, a low in early G2 and the second high in mid to late G2. Several lines of evidence suggest that the S phase peak is predominantly mRNA synthesis and the G2 phase peak is predominantly rRNA synthesis although the distinction, if correct, is not absolute (for reviews see refs 14, 15). The biphasic pattern correlates closely with the pattern of Ac_4H4 (Fig. 3) supporting the correlation between acetylated histones and transcription. About 2% of *Physarum* DNA codes for rRNA and associated spacer sequences (rDNA)[16,17]. If the G2 phase transcription is predominantly rRNA and is associated with Ac_4H4, then the G2 phase increase in Ac_4H4 from 1% to 3% implies that most of the H4 associated with rDNA would become tetra-acetylated in G2. This prediction can be tested directly.

D'Anna *et al.*[18] found low levels of H4 acetate in mitosis in CHO cells and in the present experiments the lowest values for the proportion of highly acetylated H4 also occur in mitosis, particularly in prophase, where, at M3, the proportion of Ac_4H4 falls as low as 0.4%. The absolute values at M2 are rather different from those at M3 but the direction of change in proportion is the same. The absolute difference may reflect a change in growth pattern as the plasmodium gets larger and the composition of the medium changes. These factors add a slow monotonic change underlying the larger cell-cycle-dependent changes. The amount of highly acetylated H4 in prophase is inversely correlated with phosphorylation of histone H1. As shown in Fig. 3*c*, the phosphate content of H1 reaches its maximum about 20 min before metaphase in *Physarum*[5]. Histone H1 also has a high phosphate content at mitosis in HeLa cells[19] and CHO cells[20].

There is substantial circumstantial evidence linking H1 phosphorylation in late G2 phase and prophase with chromosome condensation (for review see ref. 21). Consequently, it now seems that chromosome condensation may involve the coordinated modification of H1 by phosphorylation and of H4 by deacetylation. It follows that the extension of chromosomes after mitosis would be facilitated by histone acetylation and very rapid acetylation of histone H4 immediately following metaphase is observed.

Acetylation occurs on lysines -5, -8, -12 and -16 of H4 (ref. 1). The N-terminal region of H4 is unstructured in free solution and can be released from a nucleosome core particle by salt[22] or trypsin digestion[23] without a major effect on the integrity of the core particle. Consequently, acetylation of the N-terminal region might be expected to have very little effect on isolated single nucleosomes and preliminary structural studies of acetylated nucleosomes isolated from butyrate-treated HeLa S3 cells support this prediction[24,25]. In the bulk of chromatin, which is transcriptionally inactive, nucleosomes are packed into a higher order structure—the 34-nm coil of Fig. 4 (refs 26–28). It is a reasonable assumption that inter-nucleosomal interactions of the basic N-terminal regions of core histones are involved in generating the 34-nm coil. In this case, acetylation, particularly multiple acetylation of the basic N-terminal, would destabilize the 34-nm coil, causing a transition to a more extended

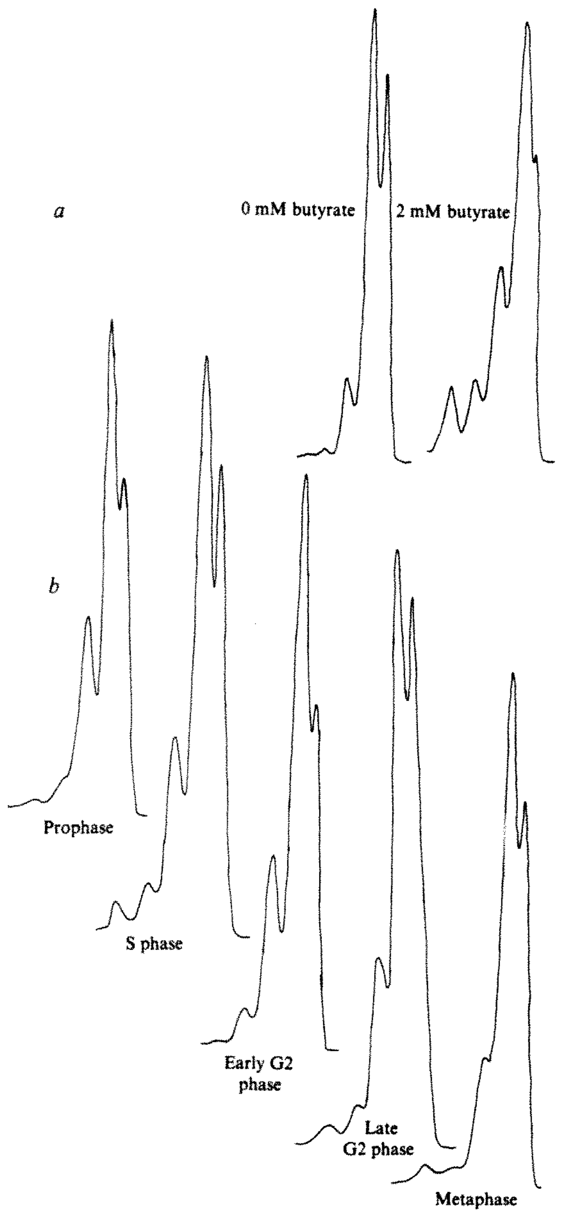

Fig. 2 Polyacrylamide gel electrophoresis of *Physarum* histone H4 in 16-cm long gels. Each profile shows five bands corresponding to 4, 3, 2, 1 or 0 acetates per molecule, reading from left to right in the direction of migration. *a*, H4 from microplasmodia grown in normal medium (left) or in medium containing 2 mM butyrate (right). *b*, H4 from macroplasmodia collected at the following stages of the mitotic cycle (from left to right): mitosis (M2 − 15 min), S phase (M2 + 1.75 h); early G2 phase (M2 + 5 h); late G2 phase (M2 + 7.5 h); and mitosis (M3). Each scan shows the H4 region of a 16-cm long tube gel electrophoresed in acetic acid plus urea[35]. The gels were stained with amido black, destained by diffusion and scanned on a Joyce-Loebl gel scanner. M2 and M3 are the second and third mitosis after fusion, respectively. The cycle time was 11 h.

conformation (Fig. 4). There is substantial evidence that transcriptionally active chromatin is in a more extended conformation than the bulk of chromatin (for example, see ref. 29) suggesting that the role of multiple H4 acetylation is to destabilize the inactive structure of chromatin (Fig. 4). Conversely, deacetylation of H4 would promote the formation of the inactive 34-nm coil and this is observed in mitosis (Fig. 3). Phosphorylation of H1 is probably involved in packing the 34-nm coils into the next order of structure (Fig. 4) and so it is inversely correlated with H4 acetylation. We anticipate one or two further orders of packing, in metaphase, leading to the metaphase chromosome and perhaps involving non-histone 'scaffold' proteins[30]. Other non-histone proteins, particularly HMG proteins[31–34], are also involved in the active chromatin structure and our present understanding of the major structural transitions in chromatin is summarized in Fig. 4.

We thank Miss S. Miller for technical assistance and our colleagues, particularly Dr R. J. Inglis and Mr A. W. Thorne, for help and discussion. The work was supported by the SRC.

The putative mRNA for subunit II of human cytochrome *c* oxidase starts directly at the translation initiator codon

Deanna K. Ojala, Julio Montoya & Giuseppe Attardi

Division of Biology, California Institute of Technology, Pasadena, California 91125

The gene for subunit II of cytochrome *c* oxidase (COII) in human mitochondrial DNA (mtDNA) is immediately contiguous, on its 5′-end side, to a tRNA^{Asp} gene[1]. Since all eukaryotic mRNAs so far analysed have been shown to have a noncoding stretch, which is presumably used for ribosome attachment[2,3] on the 5′-side of the coding sequence, it was reasonable to ask whether, in the case of the human COII mRNA, the above function is performed by the tRNA^{Asp} sequence or a portion of it, or whether this mRNA lacks a 5′ noncoding stretch. We have sequenced a 5′-end proximal segment of the putative COII mRNA from HeLa cells of about 30 nucleotides and have aligned it with the COII coding sequence in human mtDNA. Our results show that this RNA starts directly at the AUG initiator codon.

Figure 1 shows a region of the *Hpa*II restriction map of HeLa cell mtDNA[4] with the precise positions of the COII gene and of the adjacent putative tRNA genes, as determined from DNA sequencing analysis[1]. Preliminary RNA mapping experiments using the Southern[5] and Alwine *et al.*[6] methods had shown that a single mtDNA heavy (H)-strand coded poly(A)-containing RNA (RNA species 16, in the classification of Amalric *et al.*[7]) maps in correspondence to the COII gene. This RNA, on account of its size (about 800 nucleotides), its abundance, its presence in polysomes and its relatively long half life, is probably the mRNA for subunit II. Recently, using the S_1 protection

0028–0836/80/360079—04$01.00

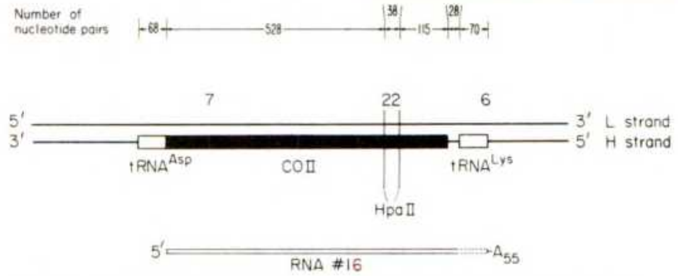

Fig. 1 Region of the *Hpa*II restriction map of HeLa cell mtDNA[4] showing the precise positions of the COII gene and of the adjacent tRNA genes. The positions of the genes were derived from the published DNA sequencing analysis[1]. The mapping position of poly(A)-containing RNA 16 (ref. 10) is shown in the lower part of the figure; the dashed portion indicates the limits of uncertainty in this determination.

technique[8,9], it has been possible to locate the 5′-end of RNA 16 more precisely, and it has been placed at about 540 nucleotides from the *Hpa*II site between fragments 7 and 22; in the same experiments, the 3′-end of the non-poly(A) segment of this RNA has been mapped in the region of the tRNA^{Lys} gene, with indications that it may overlap, in part, or possibly completely the tRNA^{Lys} coding sequence[10] (Fig. 1).

To prepare RNA 16 of high purity and in adequate amounts for sequencing analysis, the micrococcal nuclease procedure for purification of mitochondrial RNA[11] was scaled up as described in the legend for Fig. 2. Lane *a* in this figure shows the electrophoretic pattern in a CH_3HgOH–agarose slab gel, after ethidium bromide staining, of the oligo(dT)-bound fraction of mitochondrial RNA derived from about 2.5×10^9 HeLa cells. The typical pattern of the mtDNA-coded poly(A)-containing RNA species previously described in HeLa cells[7] is clearly recognizable, with the exception of the species known to be relatively short-lived and present in very small amounts (RNA species 1–4 and 6)[12,13]. RNA species 16 was eluted from the gel track shown in Fig. 2*a* and an identical track, treated with RNase-free DNase (to eliminate any contaminating DNA fragments), and re-run on a gel in the same conditions. A sharp band was observed at the expected position (Fig. 2*b*) and the RNA in this band was eluted. Material from about 8×10^9 cells, purified as described above, was labelled at its 5′-end with $[\gamma\text{-}^{32}P]ATP$ and polynucleotide kinase after dephosphorylation with bacterial alkaline phosphatase. The labelled RNA was run on a CH_3HgOH–agarose gel, a band corresponding to intact RNA 16 was observed (Fig. 2*c*) and the RNA in this band was eluted for the sequencing reactions. Mitochondrial 12S rRNA, to be used as a control for the *in vitro* labelling and sequencing technology used in the present work, was purified from the oligo(dT)-unbound RNA fraction of micrococcal-nuclease treated mitochondria and labelled *in vitro* at its 5′-end as described above.

To characterize the 5′-terminus of RNA 16, the *in vitro* 5′-end labelled RNA was subjected to a complete P1 digestion[14] and fractionation on a PEI–cellulose TLC plate. As a control, 5′-end-labelled 12S rRNA was subjected to the same analysis. As shown in Table 1, almost 92% of the radioactivity in the 12S rRNA was found to be associated with pA, the remainder being distributed among the three other nucleotides, in perfect agreement with previous work[11]. In RNA 16, the predominant 5′-terminal nucleotide (~84%) was pA. This result indicated the substantial purity of the RNA 16 used for sequencing in the present work.

Sequencing of the 5′-end proximal segment of RNA 16 and of 12S rRNA was performed by the methods of Donis-Keller *et al.*[15] and Simoncsits *et al.*[16], using base-specific enzymatic

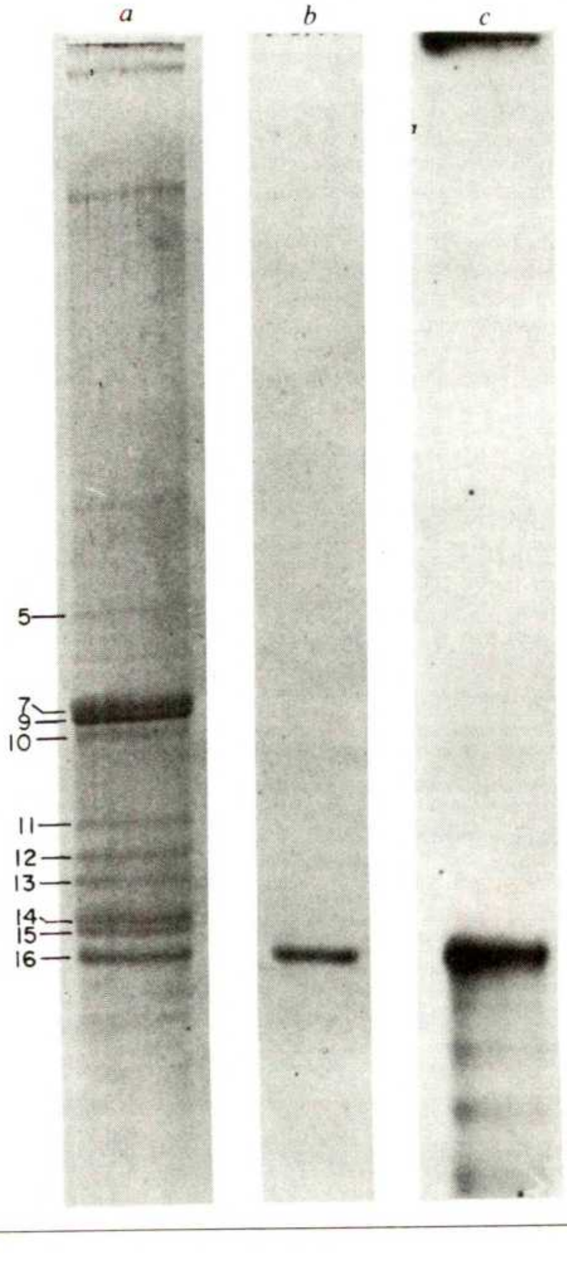

Fig. 2 Isolation and 5′-end labelling of mitochondrial poly(A)-containing RNA 16. *a*, The mitochondrial fraction from 5×10^9 HeLa cells (~30 ml packed cells) was re-suspended in 0.25 M sucrose, 0.01 M Tris–HCl, *p*H 8.0 (25 °C), 0.001 M $CaCl_2$ (1 ml per 1.5×10^8 cells), and treated with 100 units ml^{-1} of micrococcal nuclease (Millipore) at 2 °C for 30 min. EGTA was then added to 2.5 mM and, after 5 min, the suspension was diluted with 0.25 M sucrose, 0.01 M Tris–HCl, *p*H 6.7, 0.01 M EDTA (10 ml per 1.5×10^8 cells), and the mitochondria were pelleted by centrifugation at 10,000 r.p.m. in a SS-34 rotor. The pellet was re-suspended in 0.01 M Tris–HCl, *p*H 7.4, 0.15 M NaCl, 0.001 M EDTA (1 ml per 1.5×10^8 cells), incubated for 5 min at room temperature with 100 µg pronase per ml, then lysed with 1% SDS and incubated for an additional 30 min. RNA was extracted by phenol/chloroform/isoamyl alcohol (25:25:1) as previously described[7],, recovered by ethanol precipitation, denatured by heating at 63 °C for 4 min in 0.01 M Tris–HCl, *p*H 7.4, 0.001 M EDTA and passed through an oligo(dT)-cellulose column. The bound fraction was eluted, heat-denatured again as described above and re-run through the oligo(dT)-cellulose column. The final bound fraction was collected by ethanol precipitation and run through two tracks of a CH_3HgOH–agarose (1.4%) slab gel[7]. *b*, The band in *a* which corresponds to poly(A)-containing RNA 16 was identified by ethidium bromide staining and eluted as previously described[11]. After ethanol precipitation, the RNA was dissolved in 250 µl 0.05 M Tris–HCl, *p*H 6.7, 0.0025 M $MgCl_2$, 0.025 M KCl, incubated with 20 µg ml^{-1} RNase-free DNase (Boehringer Mannheim), pronase–SDS–phenol extracted and re-run through a CH_3HgOH–agarose slab gel. *c*, The RNA 16 band in *b* was eluted, ethanol-precipitated, dissolved in 100 µl of 0.01 M Tris–HCl, *p*H 8.0, and incubated at 65 °C for 15 min with 100 units of bacterial alkaline phosphatase (BRL) per µg RNA (an amount of about 0.17 µg RNA 16 was roughly estimated to be recovered from $\sim5\times10^9$ cells on the basis of its ethidium bromide staining, as compared to that of a known amount of 12S rRNA). Nitrilotriacetic acid was added to 10 mM and, after 15 min at room temperature, 2 µg of closed-circular pBR322 DNA were added as a carrier, and the nucleic acids were extracted with phenol/chloroform/isoamyl alcohol, ethanol-precipitated and dissolved in 15 µl kinase buffer (0.05 M Tris–HCl, *p*H 8.0, 0.01 M $MgCl_2$, 0.005 M dithiothreitol DTT) containing 0.5 nmol of $[\gamma\text{-}^{32}P]ATP$ (8,000 Ci $mmol^{-1}$). After addition of 2 units of polynucleotide kinase (Boehringer Mannheim), the reaction was carried out at 37 °C for 15 min and then stopped by addition of 1.0 M ammonium acetate. Carrier tRNA was then added and the mixture ethanol-precipitated and run on a CH_3HgOH–agarose (1.4%) slab gel.

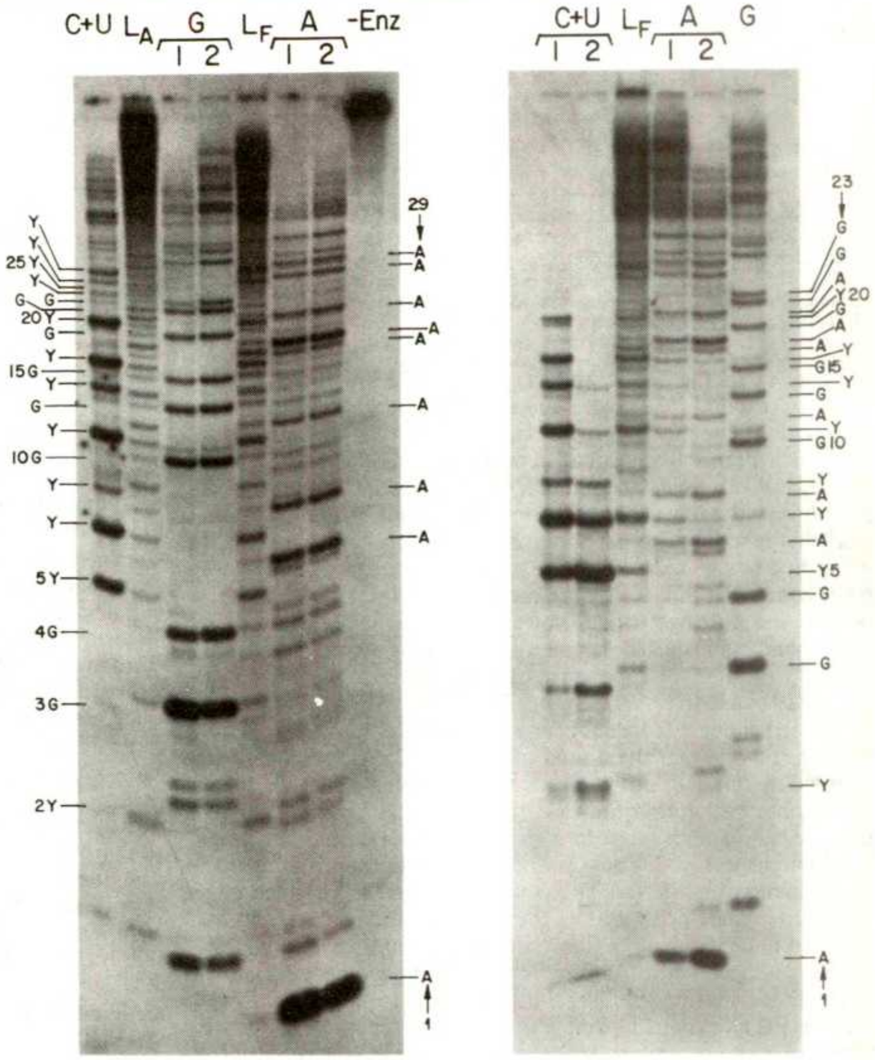

Fig. 3 RNA sequencing of mitochondrial poly(A)-containing RNA16. Autoradiograms of 25% sequencing gels (showing nucleotides 1–29) of partial enzymatic digest of 5′-end labelled RNA 16. Shown at the top of the gel are the cleavage specificities: RNase U2 (A), RNase T1 (G), RNase A (C+U), alkali ladder (L_A), formamide ladder (L_F). The reaction conditions described by Donis-Keller *et al.*[15] were used. The amounts of enzymes used (per ~30 ng RNA 16 and 3 μg yeast tRNA carrier) were, in the left panel: A 0.25 ng; T1 (1, 2), 0.10, 0.05 units; U2 (1, 2), 1.0, 0.5 units; in the right panel: A (1, 2), 0.50, 0.75 ng; T1, 0.02 units; U2, 0.15, 0.5 units. The alkali and hot formamide degradations for the formation of the ladder were performed as described by Donis-Keller *et al.*[15] and by Simoncsits *et al.*[16], respectively. Electrophoresis was carried out on thin (0.5 mm) 25% polyacrylamide (30:1 bisacrylamide)/7 M urea gels in Tris-borate–EDTA buffer at 1,000 V for 6 h.

Palit Chemistry Library SCIENCE COLLEGE 92 Upper Circular R. CALCUTTA

cleavage of the RNA followed by electrophoresis on polyacrylamide/urea gels. The RNases T1 (Sigma) (G-specific), A (Sigma) (C+U-specific) and U2 (Sankyo) (A-specific) were used for this analysis. Since the purpose of this work was the alignment of the RNA sequence with the known DNA sequence, the precise identification of the pyrimidines was considered unnecessary.

The 12S rRNA gel patterns (not shown) yielded a 5′-end-proximal sequence identical to that previously shown for this RNA species[11]. The gel patterns for RNA 16 (Fig. 3) gave a 5′-end proximal sequence which could be read for 29 nucleotides (Fig. 3). The band corresponding to the second nucleotide (a pyrimidine) was very faint in the RNA sample digested with 0.25 ng RNase A (Fig. 3, left panel), but was clearly visible in the sample digested with higher enzyme levels (Fig. 3, right panel). There were a few extra bands in the region corresponding to small oligonucleotides after RNase U2 or T1 digestion (and also after treatment of the sample with the higher levels of RNase A). These bands were in most cases less strong than the *bona fide* specific RNase cleavage products; because of this and because they did not correspond in migration to bands visible in the ladder or corresponded to obviously abnormal ladder steps (like the fairly strong band corresponding to a pyrimidine in the second lane of the right panel), they could in general be recognized as spurious bands. The nature of these extra bands is not clear; they may reflect the presence of contaminating oligo-

Fig. 4 Alignment of the nucleotide sequence of the 5′-end region of poly(A)-containing RNA 16 with the DNA sequence of the COII gene. The RNA sequence was derived from Fig. 3. The sequence of the 5′-end-proximal region of the COII gene and of the adjacent DNA segment on its 5′-side is reproduced from Barrell *et al.*[1]. Y, Pyrimidine.

Table 1 5′-terminal nucleotide analysis of *in vitro* labelled mitochondrial poly(A)-containing RNA 16 and 12S rRNA

RNA species	Percentage of total ^{32}P radioactivity* AMP	CMP	GMP	UMP
12S rRNA	91.8	1.9	2.0	4.2
Poly(A)-containing RNA 16	83.6	1.3	8.2	7.0

The 5′-terminal nucleotide was determined by exhaustive digestion of the *in vitro* labelled RNAs with nuclease P1 (ref. 14; Calbiochem) and fractionation of the products on PEI-cellulose TLC plates, as previously described[11].

* The values refer to the radioactivity which migrated from the origin. The percentage of the input radioactivity recovered from the origin was, respectively, 1.0 and 1.6% for 12S rRNA and RNA 16.

nucleotides in the RNA 16 preparation, during the 5′-end labelling reaction, or may be due to the formation, during the enzymatic or chemical degradation of the RNA, of oligonucleotides with different phosphate end-groups (2′,3′-cyclic phosphate, 2′ and 3′ phosphate). Similar bands migrating in abnormal position have been observed, previously[11] and in the present work, in the sequencing gel patterns for 12S rRNA. The reading of the first few nucleotides of the sequence near the 5′-end was made somewhat difficult by the presence of these extra bands; beyond the fifth nucleotide, however, the sequence could be read unambiguously. The sequence obtained is shown in Fig. 4, aligned with the DNA sequence of the COII gene region. The entire 29-nucleotide stretch of RNA 16 which has been sequenced appears to be colinear with the DNA sequence. The striking result is that the 5′-end of the RNA corresponds precisely to the first nucleotide of the COII coding sequence.

The observation that the COII mRNA starts directly at the initiator codon raises interesting questions about the mechanism by which the mitochondrial ribosomes attach to this messenger. In all eukaryotic mRNAs analysed so far there is a stretch of variable length which precedes the initiator codon and which is assumed to be involved in ribosome attachment[2,3]. Similarly, in *Escherichia coli* mRNAs there is a 5′-noncoding segment containing a ribosome-binding site[17,18]. A single exception to this rule has been described, namely that of the λ repressor mRNA involved in repressor maintenance[19]. In this case, it was argued that the lack of a strong ribosome binding site could account for the low efficiency of translation of this mRNA. In the case of the mitochondria from human cells (and probably from other animal cells) it is reasonable to think that the special features of their ribosomes make them suitable for binding directly to the initiator codon. It will be interesting to see whether the lack of a 5′-noncoding stretch is a general feature of mitochondrial mRNAs in HeLa cells. Preliminary observations indicate that another mitochondrial poly(A)-containing RNA in these cells, RNA 15, starts with an AUG, which may be the initiator codon for the polypeptide coded by this RNA (unpublished observations).

This work was supported by NIH grant GM-11726. We thank S. Crews for valuable discussions and A. Drew for technical assistance.

Structural and functional diversity in 4-α-helical proteins

Patricia C. Weber & F. R. Salemme

Department of Biochemistry, New Chemistry Building, University of Arizona, Tucson, Arizona 85721

Protein crystallographic studies show that many structural arrangements appear as common features among proteins which are otherwise unrelated in sequence or function. One of the more recently recognized recurring protein structural motifs is a nearly parallel arrangement of four α-helices to form a sequentially connected left-twisted bundle[1]. We describe here the geometrical properties of these structures and suggest how they relate to the functional and aggregate properties of these molecules.

Currently known proteins which incorporate a 4-α-helical bundle as their dominant structural feature include (1) the haemerythrin subunit and related monomer myohaemerythrin, which are non-haem iron-containing oxygen transport proteins derived from marine worms[2-4], (2) the apoferritin monomer, which associates to form a hollow, 24-subunit cube-octahedral aggregate functioning in iron storage[5], (3) tobacco mosaic virus (TMV) coat protein[6,7], (4) the monomeric haem protein, *Escherichia coli* cytochrome b_{562} (ref. 8), and (5) the dimeric cytochrome *c*′ from *Rhodospirillum molischianum*[9].

Figure 1 schematically compares the known 4-α-helical subunit structures in cylindrical projection. Although the molecules clearly differ in their α-helix, connecting loop, and overall chain lengths, they share a similar overall folding plan in that each is composed of four sequentially joined α-helices (A–D) arranged in a roughly fourfold symmetrical bundle having a net left-handed twist. As shown in recent treatises on helix packing[10,11], individual α-helices can be described, to a first approximation, as twisted parallelepipeds having a square cross-section. It is consequently obvious that the observed arrangement of four nearly-parallel α-helices to form an array having a square cross-section minimizes the accessible surface area of the structure as a whole[12]. Additionally, if it is assumed that these molecules fold from an intermediate state having preformed α-helices[10,13], it can be seen from inspection of Fig. 1 that all sequential helix pairs and intervening connecting loops have a net right-handed superhelical character. This is a well known chiral effect observed in several other protein structural domains[14-23] and is presumed to arise through some intrinsic property of extended polypeptide chains that confers stability on conformations having overall right-handed supercoil characteristics[24,25]. In the present case, these right-handed supercoiled connections provide the most efficient connectivity pattern for the bundle, since alternative left-supercoiled connections would necessitate the formation of a much larger loop passing around the entire molecule (Fig. 1).

Analysis of the available coordinate[26] or literature data[27] shows the helix packing in these molecules to be quite intimate, the mean adjacent interhelix axis distance of closest approach being 9.6 Å, with a standard deviation of 1.4 Å. Interhelix angles are remarkably similar, the mean interhelical angles for adjacent and diagonally related helix pairs being 162.0 ± 5.8° and −158.2 ± 7.0° (mean ± s.d.), respectively[10]. The near constancy of the adjacent pair interhelix axis angle at ~18° (180° − 162°) reflects the fact that the individual helices can only make intimate and extended packing arrangements when their axes are relatively tilted at an angle equal to twice the α-helix pitch angle (~9.0°; ref. 28). Although a detailed description of all the 4-fold symmetric, sterically acceptable 4-α-helical arrangements lies outside the scope of this communication, it can readily be demonstrated that in fact there exists a variety of

0028-0836/80/360082—03$01.00

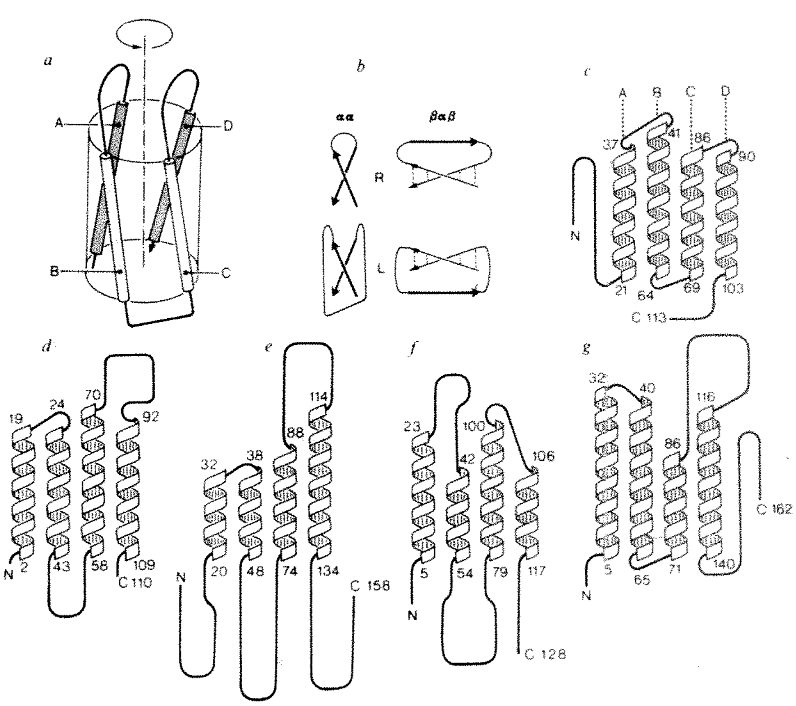

Fig. 1 Schematic representations of the 4-α-helical protein structures. *a*, Schematic representation of helical packing; *b*, schematic representation of chiral connectivity; *c–g*, examples of proteins showing these characteristics: *c*, haemerythrin and myohaemerythrin; *d*, cyctochrome b_{562}, *e*, TMV protein; *f*, cytochrome *c′*; *g*, apoferritin. Note that the connectivity pattern shown here and in Fig. 3 of the apoferritin monomer is one of two possibilities (the alternative being left-handed[5]) either of which appears equally consistent with the current electron density map interpretation (P. M. Harrison, personal communication). Each molecule is illustrated as a cylindrical projection of a common arrangement of four α-helices which are sequentially connected to form a bundle having an overall left-handed twist about the approximate 4-fold bundle axis of symmetry. This arrangement results in a right-handed (R) supercoiled connectivity pattern between adjacent helices, a feature previously observed in several other protein structural domains[14–23]. In *b*, for example, we compare right- and left-hand connected helix pairs with analogous β-α-β domains.

related packing arrangements which are both consistent with the observed geometry and have overall symmetric interactions. Further, as can be shown by an appropriate helix-net representation[28], the interhelix angle of 18° is a value which is uniquely associated with the attainment of regular periodic interactions between all helix pairs in a 4-α-helical bundle. In Fig. 2*a*, we show a packing model[28] of a representative symmetric arrangement which illustrates these points, and a similar representation of the actual packing interactions in cytochrome b_{562} is shown in Fig. 2*b*. These structures are clearly related, and so the previously reported occurrences of high internal symmetry in 4-α-helical structures[27,29] would seem to reflect the symmetrical packing requirements for helices in these bundles.

Because the α-helices in the 4-α-helical bundle structures are straight, they must necessarily diverge from their point of closest interhelix axis approach. Figure 2*c–f* illustrates this behaviour for several 4-α-helical proteins, and demonstrates both that the helical bundles of these structures have been truncated near their points of closest interhelix axis approach, and that the spatial divergence of the helices, which results as a consequence of the helix packing requirements, serves to create the internal binding pocket for the incorporated prosthetic groups.

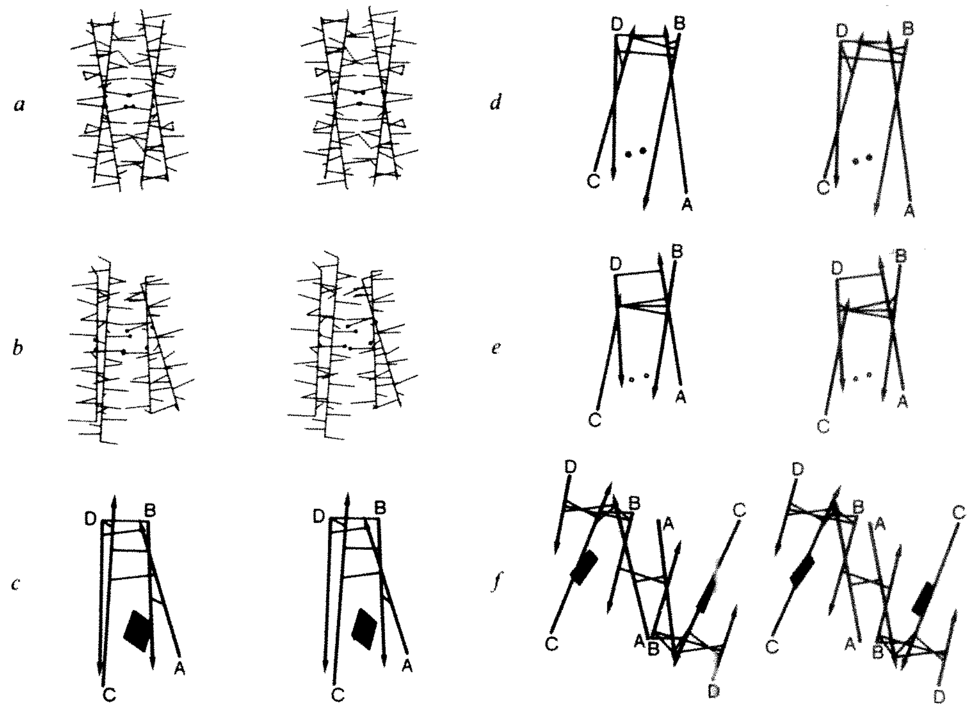

Fig. 2 Packing geometry in 4-α-helical proteins. *a*, A 'broomstick' packing model[28] in which each helix is represented as a helix axis line with 5.6 Å radial vectors[10] passing through Cβ. All adjacent helix pairs have interhelix axis angles of 18° and interaxis close-approach distances of 9.6 Å, so that the structure as a whole has the average geometrical properties of the observed structures. The structure shown has nearly equivalent local packing interactions (for example, dotted connection) which approximately repeat in the direction of the long axis of the bundle. (We note here that the interactions between the residues of straight α-helices can, at best, be only quasi-equivalent along the bundle axis. This situation differs from that observed in superhelical fibrous structures[28].) The arrangement as a whole has 222 point group symmetry, as a consequence of which each face of the bundle presents a packing surface with a diad axis of symmetry. The structure shown is only one of many possible symmetrically related arrangements which share a common overall geometry. *b* Shows a broomstick representation of the helix packing interactions in cytochrome b_{562} (ref. 8). The packing interactions in this molecule are not as regular as the model in *a*, because the residues of the real protein have different packing volumes, and the helical bundle comprising this molecule has been truncated near the region of closest interhelix approach (see *c*), with a concomitant reduction in apparent packing symmetry. Nevertheless, comparison of *a* and *b* clearly shows the helix packing in these structures to be related. *c–f* Show helix axis representations (including close approach interhelix vectors) for several molecules. As shown, all are truncated versions of a generalized 4-α-helical bundle model, which incorporate prosthetic groups in the internal cavity created by the spatial divergence of the individual helices away from their points of closest approach. An arrow indicates the N to C polypeptide chain sense in each helix. *c*, Cytochrome b_{562} (ref. 8). The position of the noncovalently bound haem group is indicated by a solid square. *d*, Myohaemerythrin[2]. Solid circles indicate the location of the bound iron atoms. *e*, Haemerythrin[4]. Iron positions are largely conjectural. *f*, Cytochrome *c′* dimer[9] showing positions of the covalently bound haem prosthetic groups.

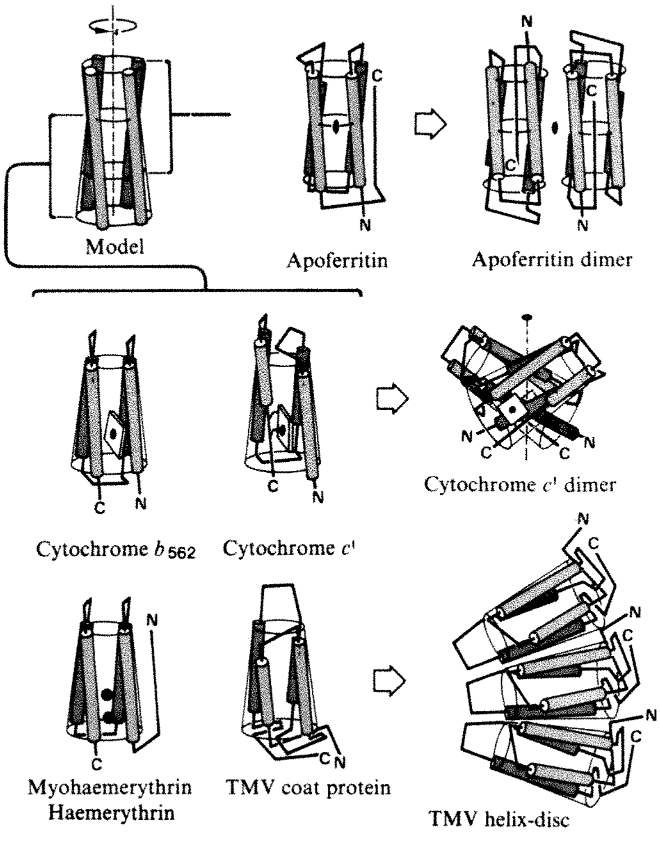

Fig. 3 Schematic representations of the 4-α-helical proteins illustrated as sub-domain arrays of a generalized 4-α-helical divergent bundle model. Broad arrows indicate the relationship between the monomeric and aggregate structural properties of the respective molecules. Details are given in the text.

Figure 3 shows the known proteins of this class illustrated as truncated variations of a generalized 4-α-helical packing model, and summarizes some additional features of their structural and aggregate properties. For example, in addition to the molecules described in Fig. 2, TMV coat protein also clearly appears to be a truncated divergent bundle structure, which instead of incorporating a prosthetic group, has a β-sheet at its divergent end which serves to 'brace' the helices apart[6]. The apoferritin monomer, in contrast, incorporates neither of these features[5] and so its helices pack more symmetrically with an equal extent of interhelical divergence at either end of the bundle. As a consequence, the most extensive pairwise monomer interaction in the cube-octahedral aggregate structure is a symmetrical dimer (Fig. 3) having interhelical interactions which are geometrically similar to those within each monomer[5]. As described in Fig. 2*a*, the symmetrical 4-α-helical packing arrangements which best satisfy the steric requirements of interhelical packing also generate diad axes of symmetry relating surface residues in adjacent helix pairs. As a result, the apoferritin subunits can pack to generate a dimeric structure whose symmetry is similar to that of the monomer.

The truncation of the divergent bundles of the remaining structures precludes the existence of diad symmetry axes on their faces, with a consequent reduction of their aggregate packing symmetry. In cytochrome *c'* for example, the monomers pack about a molecular diad axis which is independent of any symmetry elements of the monomer helix arrangements (Fig. 2).

TMV coat protein differs from the preceding molecules in that it forms aggregates having either 17- or 16.3-fold radial symmetry[6,7] in which each monomer makes different sets of pairwise helical interactions with its neighbours. However, to a good approximation, the interhelical angle between diagonally related parallel helices of the truncated divergent bundle defines the apical angle of a pyramidal prism circumscribing the molecular subunit (Fig. 3). The average observed value for this angle is 22° (180° − 158°, see above), which corresponds closely to the angle subtended by each subunit in both the TMV disk ($360°/17 = 21.2°$) and helix ($360°/16.3 = 22.1°$) structures.

To summarize, it has been shown here that the structural similarity among the 4-α-helical proteins can be attributed to what are basically physical requirements of helix packing and chiral connectivity. Consequently, it is not surprising that this structural arrangement should recur throughout the course of evolution, since it evidently possesses considerable scope for functional and superstructural diversity.

We thank Professor P. M. Harrison for providing apoferritin structural data before publication, and D. W. Weatherford for help with the computer graphics work. This work was supported by NIH grants GM21534 and GM25664, the University of Arizona Computer Center, and a Dreyfus Teacher-Scholar Award to F.R.S.

Do the chromosomes of the kiwi provide evidence for a monophyletic origin of the ratites?

Leobert E. M. de Boer

Biological Research Department, Royal Rotterdam Zoological and Botanical Gardens, Rotterdam, The Netherlands

The extensive literature on the origin of the ratites focuses mainly on three questions: are the ratites mono- or polyphyletic, did they evolve from flying ancestors, and are they primitive or advanced? Opinion tends to accept a common descent from flying ancestors for the large ratites (for a summary of ideas see ref. 1). They would have evolved on Gondwanaland some time in the Cretaceous and have become dispersed over the southern continents after its fragmentation[2,3]. However, the position of the small New Zealand kiwis, in many respects the most peculiar of all birds, is still a matter for conjecture[1,4]. The chromosome complements of the large ratites have been found to be remarkably uniform[5–8]. The chromosome set of the kiwi, described here, clearly links up with these, which may be recorded as another indication for monophyly of all ratites. It also indicates that we are dealing here with very ancient karyotypes.

The somatic chromosome complements of the five large ratites previously studied—the ostrich, emu, Australian cassowary and common and Darwin's rhea—proved to be almost identical[5,8]. Minor differences only exist in the third and fifth chromosome pair. This result seems to support a monophyletic origin of this group, and indicates an extreme evolutionary conservatism of their karyotypic morphology, because geographical isolation of their ancestors on the various southern continents caused by the fragmentation of Gondwanaland took place probably 80–90 Myr ago[2,4]. There have been no reports on the chromosomes of the kiwi. Thus, when one of the kiwis (*Apteryx australis*) at the Rotterdam Zoological Gardens recently died unexpectedly, blood and bone marrow were removed posthumously to obtain chromosome preparations (for lymphocyte culturing techniques see refs 9, 10). Possibly as a result of the infectious disease which had killed this specimen (which on postmortem observation was found to be a female), the cultures did not yield optimal results. Thus, chromosome banding studies could not be undertaken, with the exception of C-banding. Nevertheless, the available material permitted a good comparison with the data from the large ratites.

The chromosome set of the kiwi is composed of 80 chromosomes, with 6 pairs of macrochromosomes clearly distinguishable from 34 pairs of microchromosomes (Fig. 1). With the exception of the first and second pairs, all elements have a terminal or nearly terminal centromeric position. The chromosomes of the sixth pair show a weak secondary constriction in the subcentromeric region. The absence of a clearly heteromorphic sex chromosome pair is characteristic in the female specimen studied. In all other birds, with the exception of the ratites, the female is the heterogametic sex in that female individuals possess one Z and one W chromosome (which is generally much smaller) in the sex chromosome pair, whereas males possess two identical Z chromosomes. In the kiwi the fourth chromosome pair is only slightly heteromorphic, one member being consistently slightly smaller than the other. It is therefore possible that these elements represent the sex chromosomes. However, C-banding, a technique used specifically for staining the avian W chromosome, did not indicate the presence of a C-positive element among the macrochromosomes.

This exceptional situation, the absence of a clearly heteromorphic sex chromosome pair and the presence of a slight length difference in the fourth pair of chromosomes, has been found in the ostrich, cassowary, emu and rhea[5–7]. Only in Darwin's rhea have Benirschke *et al.*[8] claimed to have found a normal sex chromosome pair with a large Z and small W chromosome. In all male ratites studied, all chromosome pairs were perfectly homomorphic.

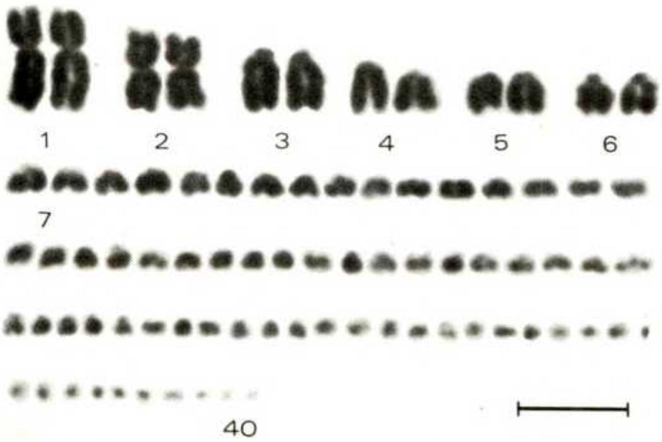

Fig. 1 Representative karyogramme of a female kiwi, *Apteryx australis*, obtained from lymphocyte culture. Note slight difference in length between the members of pair 4. The microchromosomes (pairs 7–40) have not been matched in pairs. Scale bar, 5 μm of absolute length.

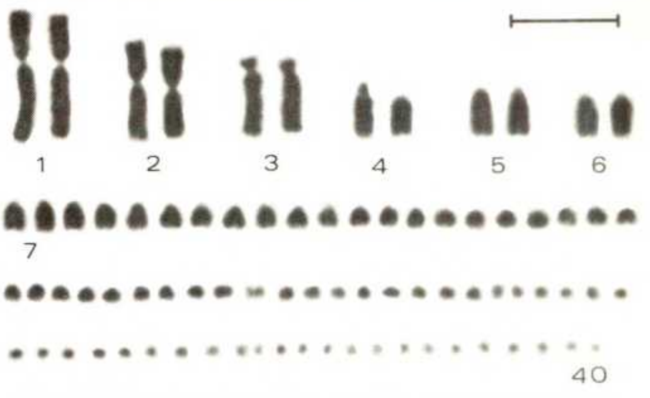

Fig. 2 Karyogramme of a female emu, *Dromaius novaehollandiae* (specifications as in Fig. 1).

The structure of the remainder of the kiwi karyotype also closely resembles those of the large ratites. In fact, the kiwi chromosomes are indistinguishable from those of the emu (Fig. 2) and cassowary. The karyotype of the ostrich differs only in the possible absence of the secondary constriction in the sixth pair and the somewhat smaller short arm in the third pair. The rhea karyotypes differ only by the submedian position of the centromere in the elements of the fifth pair.

Obviously, these gross morphological similarities need to be confirmed by detailed comparisons of chromosome banding patterns based on material from further specimens. Nevertheless, it is obvious that with its karyological characteristics the kiwi perfectly falls within the ratite group. As convergent evolution of karyotype morphology seems improbable, these findings strongly suggest a monophyletic origin of all ratites, including kiwis (and their relatives, the extinct New Zealand moas). However, one problem of this conclusion is that in cladistic[11] terms monophyly can only be concluded on the basis of shared derived characters, not on primitive ones. At present it is impossible to determine whether ratite karyotypic structure is primitive or not. Comparable karyotypes possibly only occur in the unrelated Anseriformes[7], but the sex determining system of the ratites is unique among birds. Further investigation should determine whether this system is primitive, as might be suggested by the fact that clearly heteromorphic sex chromosome pairs are absent in many reptilian groups[12]. Neither can the question of the position of the tinamous, often cited as possibly resembling the flying ancestors of the ratites, be answered from a karyological point of view, because the only report on tinamou chromosomes[13] does not include adequate descriptions or illustrations.

Monophyly or polyphyly apart, there is no doubt of the ancient character of the ratite karyotypic structure. Cracraft[4] places the ostrich–rhea bifurcation, which is generally believed to be the most recent one between the major ratite groups, as far back as 80–90 Myr ago. In the case of monophyly, the branching off of the kiwi and moa ancestors certainly would have been the earliest in ratite history. This would mean that the ratite karyotypes, especially those of kiwi, emu and cassowary, because of their uniformity, have remained practically unchanged during a period of possibly well over 100 Myr. In the case of polyphyly this would have been as long or even longer.

MATTERS ARISING

Cometary collisions on the Moon and Mercury

IT has been proposed that unusual bright and dark swirl-like markings on the Moon and Mercury may be strongly magnetized residues of recent (<100 Myr) collisions of the latter bodies with one or more cometary comas[1]. The photogeological investigations which led to this hypothesis were stimulated, at least in part, by emerging evidence that relatively high-amplitude magnetic anomalies detected with instruments on-board the Apollo subsatellites are concentrated in areas where swirls are found[2,3]. Although we agree that many of the swirls are probably relatively strongly magnetized deposits of impact-generated material, we consider that meteoroid impacts occurring over a span of time comparable to the age of the Solar System can explain their existence at least as well as can recent comet impacts. Our reasons are given below.

First, the inferred sources of medium-amplitude magnetic anomalies on the central near side[2,3] and on the far side[4] are basin ejecta materials. This result is particularly well established on the near side, where anomalies are correlated with exposed segments of primary Imbrium basin ejecta (the Fra Mauro Formation) surrounded by poorly magnetized mare basalt. Both returned sample studies and surface magnetic field investigations support the contention that ejecta materials produced during meteoroid impacts are major sources of magnetic anomalies detected from orbit[5,6]. Therefore, a special explanation for the high-amplitude anomalies involving "high-velocity imprinting of [cometary] coma fine structure" may be *ad hoc*.

Second, there is photogeological evidence that the Reiner Gamma swirl on western Oceanus Procellarum is related in origin to a nearby $3.2 \pm 0.2 \times 10^3$-Myr-old primary impact crater[3] and that some of the larger swirls in Mare Ingenii are associated with the Copernican (1–2×10^3 Myr old) crater O'Day[7]. Thus, a genetic relationship of all the swirls to the late Copernican crater Goddard A caused by a "prograde, incoming split comet system impacting the Moon" as proposed in ref. 1 is arguable. Note also that although there is evidence that many of the more conspicous far side swirls are very young, it is not known whether the young swirls are magnetized.

Third, if both the swirls and the high-amplitude magnetic anomalies are caused by comet impacts, magnetic signatures of more ancient (and more numerous) such impacts should have been detected all over the Moon. Instead, virtually all the high-amplitude magnetic anomalies detected between ±30° of latitude with the Apollo subsatellite magnetometers and charged particle instruments occur in limited selenographic regions where swirl patterns exist. The restricted occurrence of both swirls and high-amplitude magnetic anomalies within particular regions suggests a geological rather than an entirely exogenic control on their origin.

Fourth, the distribution of the largest concentrations of swirl patterns (and magnetic anomalies) on the moon is not random as expected for unusual additions of cometary matter. Specifically, as first pointed out by El-Baz[8], the most conspicuous concentrations of swirls (north of Mare Marginis and within Mare Ingenii) are roughly antipodal to the two youngest large impact basins, Orientale and Imbrium, respectively. As evidence that the antipodal relationship is not fortuitous, the two additional regional concentrations of swirls mapped in Fig. 3*b* of ref. 1 (centred at 165 °W, 23 °S and 125 °W, 20 °S) are within 5° of the Serenitatis and Crisium antipodes, respectively. Each of these four areas is known to be anomalously magnetic[9,10] and at least three of the four areas is marked by the general occurrence of unusual hilly and lineated terrain[11,12]. The latter has been ascribed either to compression at the antipode by body and surface seismic waves generated by the associated basin impacts[13] or to convergence of basin secondaries at the antipode[14]. To explain the concentrations of both swirls and large magnetic anomalies near basin antipodes, a compositional modification of the crust in areas where the hilly and lineated terrain is found has been postulated[15] such that subsequent (meteoroid) impacts on these areas result in crater ejecta which is especially susceptible to magnetization. The necessary compositional modification was proposed to be an increase in metallic iron content, as metallic iron is the ferromagnetic carrier in all sampled lunar materials.

SCHULTZ AND SRNKA REPLY—In response to Hood's comments concerning our proposed origin of the bright and dark swirls on the Moon and Mercury, we make the following comments.

First, Hood's proposal that these swirls are strongly magnetized deposits of ejecta from major cratering events is not consistent with available photogeological data. Second, although it has been argued that strongly magnetized material can be generated by an impact event[1–3], it is another matter to transport this material in an ordered fashion over long distances so as to create a magnetic anomaly during its deposition; secondary impact processes and local mixing would be expected to randomize the incoming magnetized material and prevent the building of an anomaly. Rather, the ejecta must come to rest and acquire remanence in the presence of a field; this is difficult to accomplish for impact-generated magnetic fields except perhaps for near-rim basin-sized events[2].

Specific responses to Hood's comments are as follows. First, the existence and possible correlation of medium-amplitude anomalies with the Fra Mauro Formation[4] (Imbrium ejecta deposits) are irrelevant to discussions of the origin of the swirls, other than to note that there are at least three likely processes responsible for lunar magnetic anomalies: impact-induced magnetization preserved in thick ejecta deposits, remanence acquired in the field of a primordial lunar dynamo, and our proposed cometary magnetization[5]. We stated in our report that all three (and likely more) processes have occurred on the Moon during its evolution, but that only cometary magnetization is consistent with the nature of the swirls.

Second, photogeological data do not show that Reiner Gamma is associated with the crater Cavalerius, contrary to the proposal by Hood *et al.*[4]. The swirls are surficial in character and cross a variety of features including secondary craters from Cavalerius. Cavalerius is sufficiently old for craters as large as 10 km to have superposed its ejecta deposits, excavating

0028-0836/80/360086—02$01.00

darker basalts from below. It is crucial to note that such excavations are not present on the Reiner Gamma swirls, indicating that these swirls must be much younger than Cavalerius. Furthermore, the swirls are strong forward light reflectors, in contrast to crater rays, and have a photometric phase dependence unlike any ejecta[6]. Increased forward reflection from lunar soil was observed in areas scoured by the exhaust gases from the Apollo LM descent engine. We point out that the long-term process of impact gardening homogenizes the uppermost regolith in a relatively short time, so that such a photometric effect should have disappeared in the Reiner Gamma Formation if it is an old feature. Finally, a small crater on the rim of O'Day (not the older crater O'Day) was suggested as a possible impact site related to the Ingenii swirls; relation of these swirls to the Goddard-A swirls as part of a single cometary impact event is unimportant for our proposed origin.

Third, Hood comments that if the high-amplitude magnetic anomalies are due to cometary impacts, similar features should be common because presumably many comet impacts have occurred. This is incorrect, as our proposed process affects only the upper regolith (<1 m); magnetization there will be lost comparatively quickly due to impact gardening, and viscous decay[7] of high-field remanence in the altered soil. Thus, only the most recent events, and only those associated with fresh, active comets would be observable as magnetic anomalies.

Fourth, we agree that the apparent connections between swirls, magnetic anomalies and antipodal points of some major basin-forming impacts are intriguing, but we must point out the serious difficulties encountered if these correlations are interpreted as genetically linked. First, the swirls near the crater Goddard A are not at the antipodal point of the Orientale basin, but extend 1,000 km to the east. Hilly and lineated terrains, which may be the result of focussed seismic energy[8] or convergence of secondary ejecta[9], occur at the antipodes of Imbrium and Orientale; the swirls do not. The claimed correlation of swirl positions with the Crisium and Serenitatis antipodes misrepresents the data, as swirls occur in broad bands which pass through these antipodes[5]. We have mapped swirls in these bands where photography permitted their positive identification, but south of this region the photography is extremely poor; the existence of swirls elsewhere on the Moon cannot be excluded. Finally, note that there is no reasonable candidate basin antipodal to Reiner Gamma.

Thus, we reiterate that lunar magnetization is probably the result of a variety of processes. However, the morphology and photometric properties of the light and dark swirls require both their recent origin and confinement to the regolith. They are very young features; this obviates the need to invoke magnetic shielding[10] to preserve the high albedo of their bright components.

A ?braidplain facies model for the Westphalian B Coal Measures of north-east England

It was proposed by Haszeldine and Anderton[1] that prominent sand bodies in the Westphalian B of north-east England formed as braided river sheet sands following uplift of local sediment source areas. Our studies of uppermost Westphalian A and Westphalian B sediments in the same region support differing conclusions concerning (1) the extent and significance of palaeocurrent variation, (2) petrographic differences between individual sandstones and (3) petrographic evidence that much of the sediment is recycled.

(1) We agree that successive major sandstones have remarkably diverse and sometimes opposed general palaeocurrent trends. However, we find that individual major sandstones often have widely dispersed palaeocurrents at single outcrops and over large areas have complex patterns. Such variability seems contrary to the concepts of Haszeldine and Anderton, in which braided rivers flow down tectonically tilted palaeoslopes.

The same extremely diverse palaeocurrent trends also often apply to sandstones of the interbedded 'coal bearing facies', some of which probably accumulated in the highest energy environment of small shallow water deltas. Minor divergence could be due to crevassing and to th differing orientations of sub-deltas with regard to palaeoslope, but probably not the extremes present.

We suggest that much of this palaeocurrent variability, in the major sandstones and interbedded coal bearing facies, results from minor structural and palaeotopographic control of depositional systems on a coastal plain of almost non-existent palaeoslope. Such conditions pertain over the broad expanse of the modern Mississippi delta plain (through no analogy of delta style is suggested), where river and distributary channels, and delta lobes have diverse orientations with regard to regional palaeoslope[2,3]. Subsidence and continued accumulation of similar deposits should produce the sort of complex sediment body architecture present in the uppermost Westphalian A and Westphalian B of County Durham and elsewhere[4].

(2) We have examined thin sections cut from samples of major sandstones (impregnated with coloured epoxy resin) from County Durham and coastal Northumberland. Varieties and proportions of quartz, feldspars, rock fragments and heavy minerals show few differences that cannot be attributed to grain size[5,6], diagenetic dissolution and replacement[7,8], problems of readily distinguishing small grains of untwinned feldspar from quartz and the presence of intraformational sedimentary rock fragments. The results of our point counting do not substantiate the petrographic differences between major sandstones that might be expected if they were derived from a number of differing source areas.

(3) Only a small proportion of sand within the major sandstones seems to be recycled, direct evidence for recycling being anomalous grain size-rounding relationships, grains with multiple dust rims and overgrowths, half round grains and the presence of extraformational sedimentary rock fragments[6,9,10]. Relatively fresh feldspars, including sodic plagioclases, forming on average 10% of framework grains, are hardly suggestive of recycling from low relief sedimentary source areas in humid tropical climates[6,9,11,12], neither is the original subangular nature of some framework grains. Our preliminary conclusions suggest derivation of these sandstones from a mixed source area containing granitic, low grade metamorphic and sedimentary lithologies. Devonian sediments are probably indicated by occasional rounded recycled grains with haematite dust rims underlying multiple and abraded overgrowths.

Although we welcome the stimulus to Coal Measures sedimentology provided by Haszeldine and Anderton's report, we urge caution over the application of generalized facies models the the Coal Measures, when in many areas of the UK detailed sedimentological knowledge is limited. We intentionally do not provide an alternative model for the major sand bodies within the Westphalian B of north-east England, as each sandstone requires individual consideration, in the context of its surrounding strata. Our experience in County Durham and in other British coalfields also suggests that major sandstones, apparently traceable over wide areas, may have accumulated in a number of depositional environments.

We thank the NCB and their contractors for access to opencast sites. C.R.F. is in receipt of an NERC studentship.

HASZELDINE AND ANDERTON REPLY—Heward and Fielding have highlighted some of the difficulties encountered when attempting to develop a model for the English Westphalian. Our model[1] was not intended as a definitive explanation for the details of the north-east coalfield succession, but as an alternative stratigraphic and sedimentological framework to the 'large delta' model. We proposed a low relief 'coastal plain' depositional environment crossed by many rivers. Heward and Fielding do not disagree with this general idea, but dispute some of the detailed evidence.

Deductions from measured palaeocurrents of the major fluvial facies must be made cautiously, as a wide spread of cross-bedding orientations is expected from any type of fluvial system[2–4]. Only the highest stage indicators, formed when currents are not influenced by lower stage component flows and channel-floor relief, give an accurate measure of the overall river direction[3,4]. Even these high stage current directions, fossilized by bar platform or supraplatform stratification, depend on the type of bar in the river and the method of its accretion to the floodplain[2–4]. Consequently, even from the deposits of one migrating low-sinuosity river, high stage palaeocurrents may easily vary by ±60° from the mean river orientation. These palaeocurrents will still, however, show a vector mean roughly downriver, unless accretion to one bank is dominant[4]. Coal Measures washout directions show good agreement with measured high stage palaeocurrent means, have consistent trends over large areas and have different trends from cycle to cycle. Subsidence resulting from compaction or local faulting may well have produced local palaeolopes, but these were superimposed on the regional drainage pattern. We would expect the sandstones of the coal facies to show a very great palaeocurrent variability, as lakes were probably filled from many directions (ref. 1, Fig. 1).

The sandstones examined by us contain many direct examples of recycled grains. Obviously not all recycled grains will preserve such direct evidence[5]. The apparent lack of extraformational sediment clasts is common in many modern recycled sands[5]. Note also that large quantities of fresh feldspar can survive more than one sediment cycle, and long transport distances in rapidly eroded tropical climates[6,7].

As Heward and Fielding suggest, the differences in sandstone mineralogy are not compelling in isolation, but we think that a greater degree of uniformity would be expected of sands derived from one source. Until a large-scale petrographic examination, combined with an appreciation of the relationships between petrography, the sub-environments within a river and the overall depositional environment shows otherwise, mineralogical differences and grain-size differences between sandstones (such as the anomalous coarse-grained sandstone above the Bensham seam in Northumberland) must suggest heterogeneous sediment sources.

We do not imply that all this sediment was supplied from adjacent areas, and would consider such areas as Ireland, the present North Sea and the Caledonides also contributed significantly. Any other more distant source would not account for the increasing marine influence, decrease in sediment grain size and change in river type from Northumberland towards the thickest Coal Measures in the Southern Pennine coalfields. Palaeocurrent trends of major sandstones from the east, west, south-west and north are thus in accord with our model and the overall palaeogeographical context[8].

High sediment yields from major rivers of the western Southern Alps, New Zealand

GRIFFITHS has recently estimated[1] erosion rates in the Southern Alps of New Zealand. His presentation, however, takes too little heed of published data, and has under-reported the suspended load data available.

(1) Griffiths reports suspended sediment yields from four east-coast and 10 west-coast rivers. In contrast, I have given yields[2,3] for 28 east-coast and 18 west-coast rivers, Thompson and Adams[4] have given yields from 23 of the same east-coast rivers and discussed their calculation and results in detail, and I have given yields[5] from 40 North Island rivers that have comparably high yields.

(2) Griffiths applies a traditional approach to his calculation of suspended loads. The water flow records presently available are generally good, and are quite adequate for suspended load calculations. However, I have expressed some reservations about the suspended load concentration data[4,5]. For flows less than the mean, the data are numerous (see Fig. 2 of ref. 1), but inconsequential as their contribution to the long-term mean load is slight. It is unfortunate that the sampling of flood flows is inadequate. Taking the Haast River data[1] as an example, there are 16 samples taken at less than mean flow, but only six at flows greater than the mean.

For many South Island rivers, half the suspended load is carried at flows greater than 3–8 times mean flow[4]. Because the highest flow sampled for the Haast River is only about twice the mean, considerable extrapolation of any concentration–flow relationship is required to calculate loads. Griffiths seems to have used linear regression for the relation, an approach Thompson and I rejected because of the nature of the data. Our reasons and an alternative method are given elsewhere[4,5]. This method gave the "earlier crude estimates" mentioned by Griffiths[1].

For all rivers except the Cleddau (see below) estimates by our method average 70% higher than Griffiths'. As there are no independent measurements of load in these rivers (note that both Griffiths and I used essentially the same data), and because estimates of load from point concentration samples may be in error by +100% and −50% (ref. 6), the importance of the difference is uncertain.

(3) I do not know on what additional data Griffiths' estimate of 13,000 tonnes km^{-2} yr^{-1} for the Cleddau is based, as I[2,3] estimated 275 tonnes km^{-2} yr^{-1} from concentration and flow data available up to 1977, and showed that the rate of sedimentation in adjacent Milford Sound represented erosion of about 200 tonnes km^{-2} yr^{-1}. This discrepancy of a factor of 50 is remarkable and needs to be resolved.

(4) Griffiths comments briefly on the

importance of bed load. I have derived[2,3] a bed load transport formula, checked it against some measured transport rates in New Zealand rivers, and applied it to many South Island rivers. The value of this (as of any bed load equation) is open to question, but it does estimate the bed load of the Waimakariri River as given by Griffiths[7] to within 15%. Dissolved loads have also been estimated in a general way[2,3] and, taken with the bed and suspended loads, suggest that for the Southern Alps the suspended load is 93%, the bed load 3%, and the dissolved load 4% of total river load.

(5) Griffiths neglects to mention that sampled river loads need not represent long-term average erosion rates. Some sparse New Zealand data[2,3] and observations in New Guinea[8] led me to conclude that in the northern part of the South Island, infrequent, earthquake-caused landslips could double the short-term erosion rate when averaged over hundreds of years.

(6) The obvious relationship between erosion rate and rainfall in the Southern Alps has been widely recognized. My thesis[2] contains data and discussion, showing that Fournier's[9] 2.65 power relationship between erosion rate and rainfall fits the estimates of erosion rate of the eastern slopes of the Southern Alps acceptably well. In contrast to the catchment averages used by Griffiths, the integral of local values of erosion and rainfall rate were used[4]. McSaveney[10] deduced a 2.92 power relationship and observed "rainfall is overwhelmingly the dominant influence on present erosion rates", a result later shown by Griffiths' multiple regression analysis.

(7) Griffiths' work is in general agreement with the published work cited above, and with the exception of the value for the Cleddau, I consider his estimates reasonable. There is an overall balance between rates of crustal shortening, tectonic uplift, river erosion, and deposition offshore for the South Island of New Zealand that indicates contemporary uplift and erosion of the Southern Alps[3]. The balance implies long-term erosion rates of up to 48,000 tonnes km^{-2} yr^{-1}, perhaps half of which occurs as catastrophic landslips. There seems little doubt that quite large catchments in the Southern Alps presently have erosion rates greater than 15,000 tonnes km^{-2} yr^{-1}.

GRIFFITHS REPLIES—In considering Adams' points (1) and (2) the relevant work is that of Thompson and Adams[1]. These authors assert that most of the scatter in New Zealand suspended sediment concentration versus water discharge ratings results from sediment exhaustion effects. They specifically assume that for a given river discharge the concentration on the rising stage of a flood is always higher than on the falling stage. Thompson and Adams[1] support this with results[2] from a single flood on Mararoa River. Because most concentration data have been collected on the falling stage, the authors compensate for sediment exhaustion by fitting straight lines "drawn midway between the scatter of the points" so as to give equal weight to the limited amount of rising stage data. Among the more serious deficiencies in the justification and application of this methodology are: first, on nearby Shotover River[1] scatter limits in the suspended sediment concentration rating are controlled mainly by seasonal effects. Rising and falling stage data are fairly evenly distributed (D. M. Hicks, personal communication). Second, Thompson and Adams did not identify the latter data. On Waimakariri and Forks Rivers, for example, all measurements were made on falling flood stages or at low flows: yet the ratings still are drawn midway through the scatter of the points[1]. Third, Thompson and Adams[1] do not always follow their rating definition prescription. For instance, on Acheron, Ahuriri, Clarence and Rakaia Rivers their ratings do not bisect the data scatter.

Thompson and Adams have made little use of the data: the positions of their rating lines are arbitrary; their results are not repeatable. Consequently, in this context, the relevant works[1,3] were not considered as serious references. At some sites, however, the rating definition is not too sensitive and there is the stated agreement of results[5].

Referring to his point (3) for Cleddau River suspended sediment rating, Adams uses a rating line slope of 1.7, without justification[3], whereas at his other 45 sites he assumes a value of 2.3. Even using his rating equation I cannot duplicate his yield of 275 tonnes km^{-2} yr^{-1}: instead I obtain some 2,000 tonnes km^{-2} yr^{-1}, which reduces the discrepancy to a factor of 6.5. The residual discrepancy is accounted for by his arbitrary definition of the suspended sediment rating. Similar wide discrepancies arise at other sites for the same reason. For example, in Mangatu, Waingaromia and Waipaoa Rivers, Adams[5] lists yields of 28,000, 20,000, 14,000 tonnes km^{-2} yr^{-1} respectively, whereas I calculate, using the same data, values of 7,000, 17,000, 5,000 tonnes km^{-2} yr^{-1}. Adams[3] supports his Cleddau River yield estimate with sedimentation data obtained from a single borehole in Milford Sound. He assumes suspended sediment deposition, age and areal extent of deposit and size of contributing area. This does not, in my view, constitute adequate scientific evidence.

My comments on points (4) and (5) would be too lengthy; my conclusions are similar to point (3).

With regard to point (6) Fournier's[6] relationship as applied by Thompson and Adams[1] does not fit the estimates of erosion rate acceptably well. In fact, the constant E_0, in their modified equation varies from 2,000 to 160,000 tonnes km^{-2} yr^{-1} (see Table 1 in ref. 1).

On Adams' point (7), McSaveney (personal communication) estimates a long-term yield in excess of 50,000 tonnes km^{-1} yr^{-1} in Cropp River, a tributary of Hokitika River[5]. Erosion in this catchment occurs by natural fluvial processes including frequent landslips under high intensity storms.

Finally, the units of suspended sediment concentration used in Fig. 2 and in the calculation of the coefficients in my first paragraph[5] are given incorrectly as kg m^{-3} instead of g m^{-3}. This error, however, does not enter into the results or conclusions.

Molecular clockwork

THE results of the very interesting experiment of Hartl and Dykhuizen[1] can be interpreted differently. There are three statistical problems with their conclusion that response by *Escherichia* to natural selection occurs as rapidly with generations of 5 h as with those of 2.5 h.

First, in their Table 2, basing an analysis on the last 200 h instead of the last 300, as equally justified by their own argument on the duration of the later periodic selection, would reverse the conclusion, the rate of evolution being much greater in the

0028-0836/80/360089—02$01.00

chemostats with shorter generation time. Second, non-significant differences are taken to be zero in averaging in Table 2. Using all information (ignoring significance because zero differences in fitness are not really expected and 10 of 11 non-significant differences are ostensibly positive, as expected) gives mean fitness increments of 1.78 per 100 h for shorter-period chemostats and 1.18 for longer-period ones, using the last 300 h, and 2.33 and 0.55, respectively, using the last 200 h. Again, faster evolution with more rapid generations is suggested.

Third, in competition between the same strains grown in each of the two kinds of chemostats, interstrain selection coefficients in both conditions can be compared (their Fig. 2). The trend line summarizing the results seems, however, to be an ordinary regression rather than a co-regression[2], even though the two variables depend equally on each other and there is no asymmetrical prediction involved. A co-regression would be steeper and thus suggest that elimination of weaker strains is more rapid per unit time with short generations than with longer generations; even the regression given is significant in this direction at the 0.05 level. One might want to modify the statistics of their Table 2 by this result, but alternatively, it can itself be taken as another indication of faster change with faster turnover. I do not want to imply that the results suggest a proportionality between generation number and evolutionary rate, merely a positive relationship.

Conceptually, the experiment is interpreted (even in the title) as showing that a constant evolutionary rate per unit time can be caused by natural selection. However, even if the data gave clear support to the conclusions drawn (and I think they suggest the opposite), what would be shown is that generation time does not influence evolutionary rate even under strong selection pressure. The rates of change observed were far from constant even though (perhaps because only three time intervals are involved) not significantly more uneven than rates of molecular evolution. There is no evidence to suggest a long-term approximate constancy in mean rate, as there is for molecular evolution, and an independence of evolutionary rate and generation time has long been advocated[3] from palaeontological evidence. Such an independence, to the extent it exists, is easily explained if evolutionary rate is caused largely by changes in the total environment. A stochastically constant rate of evolution is a much more difficult phenomenon to explain. This gives it power in a genetically based view of evolution; only neutralism predicts it more or less adequately in that context. However, if we take ecology seriously with respect to evolutionary change, a natural (but still unproved) explanation for the observed degree of constancy emerges[4]. It is quite consistent with the observed large short-term differences[5-7] in evolutionary rates, as neutralism may not be[7].

DYKHUIZEN AND HARTL REPLY—Before discussing the particular points raised by Van Valen, we wish to emphasize that the molecular clock is sloppy[1], so exactitude should not be expected. It would be wonderful to carry out such experiments for 500 years (or, better yet, 500 Myr). In such a long time span, different results might very well be obtained. We have achieved only 500 h. Nevertheless, our data have remarkable internal consistency for experiments of this sort, and the formal congruence between the characteristics of our results and of the molecular clock are too striking to ignore. Also, we do not suggest that the environment is unimportant to the rate of evolution. The chemostat is a novel environment for *E. coli* K2, and it is likely that the large initial selection is due to this change of environment. It is also possible that the average rate of selection would decrease over time in the constant environment of the chemostat. Chemostats could be run for 2,500 h to see if this supposition is true. If true, it implies that environmental change is required to keep the selective clock wound.

Van Valen has questioned why we chose to analyse the last 300 h rather than the last 200 h. Most of our argument is actually based on the full 500 h as evidenced by the statement "The overall [that is, 500 h] average fitness increment per 100 h is 2.99 in the 2.5 h chemostat and 3.00 h in the 5.0 h chemostat"[2]. (Incidentally, if one treats all fitness differences as if they were significant, as Van Valen suggests, the corresponding averages are 3.28 and 3.05.) We presented the averages for the period 200–500 h only to show that we were not being misled by the large fitness increments that occur in the first 200 h. Van Valen points out that if only the last 200 h are taken for analysis, then it looks as if the 2.5 h strain is evolving faster. But this ignores more than half of the experimental measurements, and it contradicts the conclusion from the entire data set. By using a selected subset of any data, one can contradict any conclusion whatsoever.

There is, however, a better way to settle the issue, which is by direct competition between strains that have evolved for long periods at either a 2.5-h or a 5.0-h generation time. For strains that had evolved for the full 500 h, the largest fitness difference is observed when the experimental test is carried out in a 2.5-h chemostat; the 2.5-h strain is favoured, to be sure, but the fitness difference is a mere 5%. This amount of genetic divergence over 500 h is very small indeed. Moreover, when tests are carried out in a 5.0-h chemostat, selection actually favours the 5.0-h strain. These observations are difficult to reconcile with a presumed more rapid rate of evolution at a 2.5-h generation time[3].

The data in our[2] Fig. 2 are not relevant to the issue of rate of increase in fitness; they pertain to whether measured selection coefficients depend on the conditions of measurements. If the slope of the line in Fig. 2 is truly greater than 1.0, as Van Valen suggests, then we have actually overestimated the rate of increase in fitness in 2.5-h chemostats by about 25%, so our original conclusion receives additional support. Moreover, Van Valen's suggestion of co-regression is well taken. The co-regression line[4] has a slope of 1.5, which, if taken literally, calls for a correction of about 35%, so our original conclusion is more forcefully justified by Van Valen's own technique.

In short, our results indicate that the rate of increase in fitness is related to the amount of time spent in the chemostat rather than the number of generations. The issue is clearly an important one, and we hope that this exchange with Van Valen will encourage more of such experiments to be undertaken.

Matters Arising

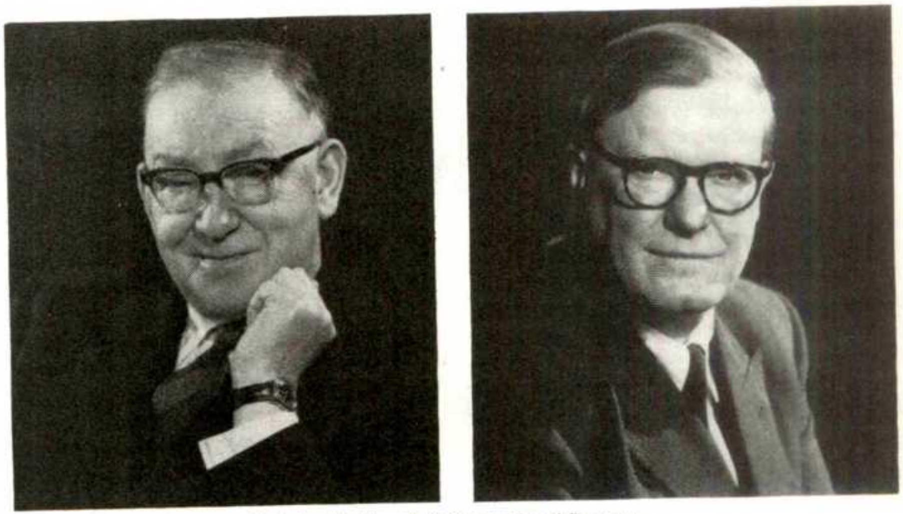
Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

BOOK REVIEWS

Certainty into doubt: 25 years of nuclear debate

Alan Cottrell

The Nuclear Power Decisions: British Policies, 1953–78. By Roger Williams. Pp.365. (Croom Helm: London, 1980.) £19.95. Available from Biblio Distribution Centre, Totowa, New Jersey, $49.



Sir John Cockcroft (left) and Lord Penney — "heroes" of the 1950s and 60s.

THERE IS a saying in the nuclear industry that the reactor you choose is always the best one. It becomes the best one because you work on it, solve its problems, improve it, develop and adapt a whole technology to it, all of which gives it an edge over its rivals. There are certainly grains of truth in this, but the irony is that different countries have different 'best' reactors and hang on to their choices grimly through thick and thin. Today we have each of the three original reactor-producing countries firmly entrenched in its own concepts of thermal reactors: the gas-cooled types, Magnox and AGR, for the British; the light-water ones, PWR and BWR, for the Americans; and the heavy-water one, CANDU, for the Canadians.

It is interesting to follow these deep, insurmountable, trenches back in time to their earliest beginnings in the 1940s as slight traces across the smooth face of the then infant nuclear era. There were the Americans using light-water cooling in their early Hanford reactors, choosing it for its simplicity and because they had the empty spaces in which to site these possibly dangerous plants. From this early background they went on to light-water pressurized reactors for propelling submarines, out of which grew the modern pressurized-water and boiling-water civil reactors. Again there were the British, with their lack of large rivers for coolant in very remote and unpopulated regions, choosing gas-cooling for their early Windscale military reactors, which likewise set them firmly in their own groove; and yet again there were the Canadians, keen to make the best use of natural uranium and so being led to heavy-water, to which they became equally heavily addicted. Only the French, in switching from gas cooling to light-water cooling, dared to jump over into another trench.

Much of this is brought out in Roger Williams's splendid book, *The Nuclear Power Decisions,* which discusses the major British decisions in the civil nuclear field, and the way they were made, between 1953 and 1978. Mostly, the book deals with the history of the Advanced Gas-cooled Reactor (AGR) — of how, despite its various imperfections and vicissitudes, it successfully fought off all threats from every water-cooled rival, basically because it was a gas-graphite reactor, a British concept with British technology and expertise, a direct descendant of the Windscale, Calder Hall and Magnox reactors. Williams takes the reader carefully and clearly through the history of this, giving full weight to all the technical, economic, political and, not least, personal factors involved in the decisions. The sound of those old debates of the 1950s and 60s, now half-forgotten, comes thundering back with the reminders of the great speeches by the heroes of that period — Hinton, Penney, Cockcroft, Plowden, Sherfield, Coleraine, Stanley Brown and others; as well as the clash of argument between the AEA and the CEGB. We are also reminded of the amazing surefootedness of that early period, of the launching in the mid-1950s of a huge programme of Magnox reactors even though their prototype, Calder Hall, was still one year away from completion. Contrast that with the snail-like approach we are making today towards the Fast Breeder Reactor. How did we lose our nerve? Williams is too polite to say but he does make a vigorous plea in his final chapter for a system of public accountability that would make civil nuclear energy as acceptable to the general public in the 1980s as it so obviously was in the 1950s.

Perhaps the difficulties of the AGR had something to do with it, causing us to doubt whether our 'best' really was the best of bests. Williams takes the reader through the dense jungle of AGR politics with immense skill and clarity, especially in regard to the economic and political factors. Despite the intentionally non-technical nature of the book, more could perhaps have been made of the technical differences between AGR and the water reactors, and their significance, particularly from the point of view of safety, for these factors do have important weight in the decision-making. Nevertheless, the account is a very fair and well-balanced one, which is no mean feat in a field where emotions run so high that one distraught civil servant felt impelled to complain that it was impossible for anyone to remain impartial where the choice of reactors is concerned.

The final section of the book deals with the 1978 Windscale decision. This is not only a change of subject — the expansion of the nuclear reprocessing plant — but even more a reflection of the change of mood since the 1950s. No longer is there the gung-ho approach of the early White Papers on reactor programmes. Instead we are in the era of doubt, of public enquiries, of Mr Benn's hesitations, of the cautionary remarks of the Flowers Report, and of the campaigns by the Friends of the Earth and other anti-nuclear groups. So much has the native hue of nuclear resolution been sicklied o'er by the pale cast of thought. And this leads to Williams's final chapter on public accountability and his "conviction that Britain can have a much more successful industrial future than she has had an immediate past, especially where nuclear power is concerned". A book strongly to be recommended. □

Advances in research on evoked potentials

D. Regan

Evoked Potentials. Edited by C. Barber. Pp. 614. (MTP Press: Lancaster, UK, 1980.) £29. *Clinical Uses of Cerebral, Brainstem and Spinal Somatosensory Evoked Potentials.* Edited by J.E. Desmedt. Pp. 354. (Karger: Basel, 1980.) SFr 138, $82.75. *Cognitive Components in Cerebral Event-Related Potentials and Selective Attention.* Edited by J.E. Desmedt. Pp. 322. (Karger: Basel, 1979.) SFr 118, $70.75.

IT HAS been known for almost 100 years that the human brain continuously generates an electrical oscillation called the electroencephalogram (EEG) that can be recorded from electrodes held onto the scalp. The EEG can reach an amplitude of 100 μV, so that the brain's 0.1-10 μV responses to auditory, visual, tactile or olfactory stimulation are usually hidden in the EEG. Consequently, these electrical responses to sensory stimulation, called evoked potentials, were almost unexplored until automatic signal-processing devices, developed in the 1950s, were used to separate evoked potentials from the brain's background activity. Part A of Barber's book is an excellent, concise survey of these signal-processing techniques and evoked potential methodology.

The three books reviewed here together cover all the main directions of current evoked potential research. Many contributors emphasize the present clinical value and future promise of evoked potential recording as an effectively risk-free means of objectively testing hearing, vision and spinal cord function. Clearly, a battery of objective sensory tests would meet a need, particularly with neonates and young infants, where the available methods for testing sensory function are imprecise. In adults, evoked potential tests can distinguish between organic and psychogenic disorders, and practical successes with adult patients are described by authors in all three books. In particular, short-latency evoked potentials recorded from auditory brainstem structures have proved their worth both in the neurological clinic and in assessing hearing disorders, and evoked potentials produced by visual patterns are widely used as an aid to diagnosing multiple sclerosis. Auditory brainstem responses are a promising means of testing infants' hearing, and a technically difficult method for recording from electrodes over the spinal cord has been successfully used with infant patients, but so far visual evoked potentials seem to have had comparatively little impact on the visual testing of infants and the management of amblyopia. Part A of Barber's book identifies limitations in our understanding of visual evoked potential generation that must be overcome if the method is to fulfil its exciting promise in paediatric neuro-ophthalmology.

Evoked potential recording is the only widely available, risk-free means of objectively exploring the activities of normal human brains (analysis of the brain's magnetic field is still at an early stage of development). Consequently, evoked potential recording has a special appeal to scientists interested in aspects of brain activity that may be peculiar to the human species. Rather than studying evoked potentials generated by sensory stimuli, a second line of research explores scalp potentials produced or modified by thinking processes. Several authors in Desmedt's book on cognition show how evoked potentials can be used not only to study the brain activities associated with mental evaluation of incoming sensory information, but also how to study cognitive aspects of brain function including selective attention.

All three books are collections of contributions by different authors, each of whom focuses chiefly on his own research area. Although this style of book can be assembled more quickly and with less individual toil than is the case when the writing is undertaken by only one or two authors, there are disadvantages for the reader. These include greater difficulty in following a coherent thread through successive chapters, and some unevenness in the standard of different authors' contributions. Since each of the books edited by Desmedt addresses a restricted topic these drawbacks are less evident than in Barber's book. Desmedt's two books provide researchers and clinicians with summaries of current research in cognitive evoked potential studies and in somatosensory evoked potentials that are as useful as any available. However, it is a pity that substantial linking commentaries were not incorporated, since these would have made both books more effective as introductory texts. Although its inclusion may have delayed publication, the edited discussion on pattern responses in Barber's book adds considerably to the value of the text. Several more such discussions could have been added with advantage.

Barber's book is based on the 1978 evoked potential conference held in Nottingham, and resembles in some ways a book based on the 1974 Brussels conference (*Visual Evoked Potentials in Man.* Edited by J.E. Desmedt. Clarendon: Oxford, 1977). Some impression of progress in evoked potentials research can be obtained by comparing these two volumes. What emerges is that the relation between cognition and long-latency evoked potentials is more complex than was thought to be the case in 1974; it now seems that several late waves exist, differing from one another in their brain origins and psychological correlates. Our basic understanding of visual evoked potentials advanced substantially before 1974, but progress seems to have slowed since then. The few researchers attempting to develop evoked potentials as much-needed objective measures in psychiatry have continued to encounter formidable problems including the broadness of clinical diagnostic classifications. In contrast, the use of visual evoked potentials in the neurology clinic, a research technique in 1974, is now routine in a large number of hospitals. Perhaps the major new thrusts in basic research and in clinical applications have been in auditory brainstem and somatosensory evoked potentials, and these topics are well covered both by Barber and by Desmedt. □

Protein synthesis from start to finish

P. J. Ford

From DNA to Protein: The Transfer of Genetic Information. By M. Szekely. Pp. 284. (Macmillan Press: London, 1980.) Hardback £18, $35.95; paperback £9.95.

From DNA to Protein is an up-to-date (early 1979) account of that fascinating but ill-defined area of biology comprising some genetics, some biochemistry and some macromolecular structure. The book has been written for advanced undergraduates and postgraduate students, but is also intended for research workers wishing to keep up with molecular biology.

My initial reaction to the contents pages was very favourable since the book is logically ordered, starting with a description of DNA structure and replication, followed by transcription and messenger RNA structure and leading into a discussion of translation. There is also a chapter on methods of nucleotide sequence determination which, for some undergraduate teaching purposes, might be too specialized. Such detailed attention nevertheless does indicate the overwhelming role of technology in forcing advances in this area, a point which I think cannot be made too often.

Reading the book in more detail I found that descriptions of particular systems were generally easily followed although there are many places where more careful editing would have improved communication. Some more obvious errors might also have been removed such as the "thousands (of ribosomal RNA genes) in *Drosophila*" (p. 16) or more seriously the suggestions that satellite DNAs are small molecules (p. 28) and that yeast has a single chromosome (p. 34).

On p. 41 there is the ambiguous statement that "In higher organisms in which the enzyme patterns of the different cells are fairly constant, the protein genes are not part of operons. They are dispersed in the chromosome, transcribed separately and their expression is in most cases individually controlled". This is the point at which the author comes nearest to discussing the fundamental problem in eukaryotic gene regulation, which is how an apparently constant genome manages to produce such a diversity of cellular structure and function during development and differentiation. However, the theme of coordinate gene regulation in eukaryotes is not pursued. Nor is any attempt made to rationalize known genetic linkage maps in terms of gene regulation. The passage also serves to illustrate a general weakness of the text, which shows a preoccupation with minutiae and failure to state basic problems clearly and extract a useful synthesis of ideas from the welter of information. In particular I had expected a discussion of gene structure on the basis of the discoveries of overlapping and split genes, since this is promised on the dust cover. Although overlapping and split genes are mentioned on several separate occasions, there is no single passage which attempts to draw together all the observations and to deal with their consequences for the control of messenger RNA synthesis and for the evolution of protein structures.

Some specific topics which I would have liked to see mentioned are transposition and insertion elements as model mechanisms for moving DNA within and between chromosomes; a more detailed treatment of lambda phage as a model for switching between two alternate (lytic or lysogenic) types of development; a treatment of gene numbers in terms of rate limits to transcription; consideration of immunoglobulin genes in relation to specific reorganization of DNA during differentiation; and some discussion of secretion which involves a hydrophobic amino-terminal signal peptide enabling proteins for secretion to cross membranes.

For students the reviews of DNA replication, transcription and translation should be useful and are well referenced up to 1978. Although these chapters relate almost exclusively to prokaryote systems they do give comparisons with eukaryote translation mechanisms, eukaryote RNA polymerases and eukaryote DNA replication mechanisms. The other chapters on the structure of messenger RNA, the structure and function of ribosomes and on transfer RNA are perhaps too specialized for all but the devotee of macromolecular structure and function. □

P. J. Ford is a Lecturer in the Department of Molecular Biology at the University of Edinburgh.

1937, 1951, 1976 — progress in crystallography

D.W.J. Cruickshank

X-Ray Analysis and the Structure of Organic Molecules. By Jack Dunitz. Pp. 514. (Cornell University Press: 1980.) $55, £36.

THIS BOOK has developed out of the Baker Lectures given by Jack Dunitz at Cornell University in the fall of 1976. Once again the publication of a set of the Lectures allows them to be appreciated by a far wider audience than the chemists of Cornell. This volume immediately brings to mind Linus Pauling's influential Lectures of 1937, "The Nature of the Chemical Bond and the Structure of Molecules and Crystals", and J.M. Robertson's notable contribution of 1951, "Organic Crystals and Molecules". Crystallography and organic chemistry have developed enormously in the last quarter century, so that whereas in 1951 Robertson could discuss a large proportion of the 200 or so organic crystal structures then known, in 1976 it would have been impossible for Dunitz to survey 16,000 structures in like fashion.

Dunitz's book is in two parts: "Crystal Structure Analysis" and "Molecular Structure". The first part is a fairly complete guide to current methods of determining the crystal structures of small or medium-size molecules (not proteins). A score or two of books must have been written on crystal structure analysis, but Dunitz's volume is more attractive than most of the others. This is because of the flowing informal style and the penetrating insights and asides of a master of the craft. I suspect his treatment will prove somewhat too professional for most of those chemists he wants to help read the crystallographic literature, but it will be invaluable for young (or not-so-young) crystallographers seeking an overview of the main parts of the subject.

Among the interesting features is a discussion of the frequency of occurrence of particular space groups and Kitaigorodsky's explanation of this in terms of possible molecular packing arrangements. On p.136 we learn of the caesium salt of boromycin, the absolute configuration of which was established before its structural formula. On p.143 we read of the flurry caused in 1972 by Tanaka's claim that all absolute configurations determined by X-ray analysis were wrong and should be changed into their antipodes. Tanaka's claim proved ill-founded, but his error was a happy one for it led to new and independent proofs of the correctness of the Bijvoet method. There is a helpful and well-titled section on hazards of oblique coordinate systems. Both this and the section on thermal motion analysis contain useful worked examples.

Unfortunately the treatment of Fourier transforms is marred by a misprint at a critical point on p.30, and by a failure to make clear whether the inverse transform relates to the minus sign in the exponential argument or to the transformation from **R** space to **r** space. Dunitz is a Lewis Carroll fan and he concludes his summary of simple theorems about Fourier transforms with a quotation from *Alice*:

> "What *is* the use of repeating all that stuff", the Mock Turtle interrupted, "if you don't explain as you go along? It's by far the most confusing thing I have ever heard!"

Dunitz must have had a premonition of trouble on the printed page!

The second part on molecular structure contains four chapters, of which the first, "Crystal Structure Analysis and Chemistry", is both the most substantial and the one of greatest general interest. Dunitz first traces the explosive growth of information on molecular structures and stresses the utility of the computer-based files of structural data collected by the Cambridge Crystallographic Data Centre. He reminds us of the triumphs of classical organic chemistry in the determination of structural formulae, but uses patchouli alcohol as an example of an unexpected contradiction. He reports on conformational analysis, solid-state chemistry and reaction intermediates — the latter illustrated by the remarkable structure of $CO_2(CO)_4(H_2CBu^t)(C_2H_2)$ determined by Mills and Robinson in 1964. Then comes a discussion of molecular potential energy surfaces, which leads on to Dunitz's structural correlation principle whereby the numerous slightly differing 'still' pictures of the same structural fragment in different crystals are used to infer a chemical reaction path. Nucleophilic addition to carbonyl groups is used as one of the examples of this principle.

The remaining chapters include a good account of investigations into the electron-density distributions in molecules, a very clear exposition of the geometrical aspects of the closure constraints in cyclic molecules and an elegant discussion of symmetry in conformational maps.

Dunitz learnt his crystallography in Glasgow and Pasadena. Robertson and Pauling can be well satisfied with the volume their former protégé has now placed alongside their own in the Baker Lecture series. □

D. W.J. Cruickshank is Professor of Chemistry (Theoretical) at the University of Manchester Institute of Science and Technology, and was formerly General Secretary and Treasurer of the International Union of Crystallography.

11 September 1980

More ups and downs for US science

Like the Grand Old Duke of York (the one who marched his men to the top of the hill and then down again), President Carter seems bent on making those who depend on his administration for financial support survive successive spells of euphoria and depression. This, at least, is how the chopping and changing on the budget for the coming year (which starts at the beginning of next month) must seem. The tale, chronicled at length in the past few months, is especially bewildering for the research community, which is aware both of the need to be able to plan ahead and of the attempts by Congress (at the urging of the Administration) to devise some way in which the basic research budget can be made less vulnerable to annually changing fashions.

The tale goes like this. In January, the President's budget request to the Congress, in aggregate unbalanced and therefore a disappointment to those who had taken Mr Carter's election promises seriously and also disappointing to foreign exchange dealers, provided for a substantial growth of real support for research and development. The total cost of research and development to federal agencies was to grow rather more quickly than inflation, but basic research was to be treated even more generously with an extra 3 per cent in real terms between the two financial years. The word went out that these provisions were a measure of the Administration's commitment to the importance of basic research. Spirits soared at the National Science Foundation and the National Institutes of Health, which were to be dealt with especially generously.

These spirits did not last for long. Before Congress had time to buckle down properly to its annual and needlessly tedious scrutiny of the proposals, economic crisis was the order of the day. With the prospect of increased inflation, people took to borrowing from the banks to buy goods on tick, with the result that the money supply increased dramatically. Professor Milton Friedman's followers were no doubt kept awake at night with worry, and the dollar slumped on the international exchanges. So the White House itself took a knife to the budget. In total, the discretionary parts of the budget were reduced by some 8 per cent, credit was restricted and interest rates raised. The word went out that these steps were a proof of the Administration's commitment to the battle against inflation. Fair play, research and development did relatively well. Basic research was especially well favoured, but the prospect of growth melted away. Some were brave enough to suggest that this relative leniency was a proof of the Administration's belief in the importance of research and development.

Now the troops are back at the top of the hill again (see *Nature*, 4 September), or are at least half way there. At the end of last month, President Carter announced his "Economic Program for the Eighties" which is a complicated mixture of tax cuts, incentives to further industrial investment, provision for helping people adjust to rapidly changing economic circumstances and — here comes the surprise — more money for research and development, especially for basic research. For practical purposes, the new proposals put the science budget where it was in January, but also give Dr Frank Press, the President's Science Advisor, an extra $255 million to allocate to new projects. Moreover, the President has said that there will be a further increase of 3 per cent on basic research expenditure in the following financial year (beginning on 1 October 1981). So, predictably, the word has gone out that the Administration's commitment to the importance of research and development, and to basic research in particular, has been demonstrated once again. The only fly in the ointment is that much of this promise will not become reality until next January, when President Carter hopes to introduce his next budget resolution to Congress. There is as yet no sign of what Mr Reagan would do if he had the responsibility.

Several questions arise from this curious tale, not the least of which is whether the Administration is really serious in its protestations that the interests of research and development, particularly of basic research, lie close to its heart. The issue is complicated because the President's motives for the timing of his announcement of the new programme of economic recovery are dubious, to say the least. At the beginning of an election campaign, and with his chief opponent calling for a substantial tax-cut across the board, it would be asking too much of flesh and blood to stick to an austere programme of economic restraint. Moreover, the package of measures now announced will win some votes. Salary-earners will benefit from the proposed reduction of social security taxes (although the US Treasury will have to borrow from the market to meet the obligations of the years ahead). Business (especially small business) will benefit from the increased depreciation allowances on capital expenditure. But is it realistic to suppose that there are votes in the promise that the budget for basic research should be restored to that first asked for last January, especially when the decision is for now only a promise? On balance, this part of the package appears as disinterested as anything of the kind could be in an election year. Whatever next January may bring, the Administration's protestations must be taken seriously. No doubt a large part of the credit lies with Dr Press.

The question therefore arises as to whether the Administration is going about its intended task in the best way. Protestations and promises, after all, do not make programmes. The chief novelty in the plan for spending the extra £255 million is that the Administration intends deliberately to stimulate industrial research and development. The first thing to say is that the new commitment derives from an idealistic view of the place of research and development as the root of industrial innovation and productivity. (Idealistic, it should be remembered, does not necessarily mean näive.) Next to the question as to whether it will be possible to vote with a good grace for either of the principal candidates in the coming election, Americans now appear to be mostly preoccupied with the decelerating growth of industrial productivity in the United States. Germany, and even Austria, are becoming more productive faster, and nobody can hold a candle to Japan. The fact that countries such as Britain and Italy are doing even worse than the United States is not a comfort but a warning. But it is also known that the decline of the rate of growth of productivity has been accompanied by a decline of industrial spending on research and development. But is not industrial research the fount from which innovation and productivity spring? And if industry lags, can the government not make good the deficiency by spending public funds on research and development linked with industrial needs?

The calculation is straightforward, familiar and good-hearted. The fact that governments in most other industrialized nations have, in the past thirty years, come to the same conclusions, turned them into policies and then been disappointed in the results does not necessarily imply that the new American initiative will fail. The framework of research is more vigorous and more flexible than elsewhere, and in any case there are lessons to be learned from overseas. No doubt the Administration (if it gets the

0028-0836/80/370095-02$01.00

chance) will avoid the trap of thinking that research and development will enable inherently uneconomic industries to survive. At this stage, the most important need is that the attempt to reinvigorate American industry by research and development should be openly regarded as an experiment, not as a sure-fire remedy. American governments have some experience of the support of industry by directly financed research programmes, but the conspicuous successes are in fields such as agriculture. The most serious danger is that, presented with the opportunity to help shape the pattern of public support for industrial research and development, Congress will fail to resist the temptation to play pork-barrel politics with a programme that deserves a fair chance.

The record of Congress in the past six months has, after all, been no better than that of the Administration. Chopping and changing is bad for all public programmes where continuity is essential, and especially for research and development. By amending its budget for the coming financial year almost as frequently as the British budget was amended by Mr Denis Healey in his heyday as Chancellor of the Exchequer (between 1974 and 1976), the Administration has inevitably damaged confidence and continuity among researchers. Congress has a right, even a duty, to scrutinize the way in which public funds are spent — that is a large part of its constitutional role. On technical matters, however, Congress is inclined to make judgements of budget proposals on the basis of their declared objectives. Feasibility matters less. This year, no doubt because it is an election year, Congress has been unusually trying. One result is that the budget for the coming financial year beginning in a few weeks is still far from settled. Is it not time that the US government as a whole found a less chancy (and costly) way of deciding how funds should be spent on research and development? As things are, there can be no certainty that the brave schemes the Administration has been hatching will be given a fair trial.

That the schemes themselves are adventurous, nobody will dispute. Apart from the restoration of the March cuts of the January budget, which will mean that agencies such as the National Science Foundation and the National Institutes of Health will have more to spend on research grants, there are plans to re-equip university laboratories, to set up "generic technology centres" in partnership with industry and to foster relationships between industry and universities. Sensibly, there are to be consultations between the Administration and the interested parties — universities, industry, and professional and scientific societies — before final decisions are made. In other words, the Administration seems anxious to avoid the trap of imposing a theoretical framework of its own ideas on the pattern of its new spending. That is a sign of grace but also one of the best ways of avoiding obvious pitfalls.

In the long run, however, success will also be determined by broader considerations, many of which have been overlooked in the design of Mr Carter's economic recovery package and the subsequent discussion of it. Whatever may be the merits of the individual components in the package, there is no doubt that the overall effect will be to increase the government's deficit by between $30 billion and $50 billion a year. New expenditure, as on research and development, is tiny compared with the cost of the proposed tax concessions and depreciation allowances. Paradoxically, all this has come about when figures suggest that money supply is increasing again, and rapidly. Neither Keynesians nor monetarists would think this a time when the American economy needs further stimulation by deficit financing. Indeed,the consequence of the economic recovery package (if enacted) may be more inflation and more of the damaging consequences for innovation and investment which have become apparent in the past few years. In short, the underlying problems of American industry may be the problems now unhappily familiar elsewhere.

Scares about genetic manipulation

One of the hopes, perhaps unrealistic, of this new decade was that the arguments about the hazards of this or that new scientific development would be couched in more moderate language than used to be the fashion in the 1970s, when Dr George Wald was one of those given to drawing analogies between would-be genetic manipulators and Hitler's would-be eugenicists. And it is true that, for the most part, the argument about genetic manipulation has taken a turn for the rational, partly because experience has shown that the hazards are less serious than some had fairly thought but also because it has become clear that many of the problems thrown up by the practice of genetic manipulation are different in kind from those originally foreseen — problems occasioned by commercial links between academic scientists and industrial companies, for example (see *Nature* 24 July). Yet, it appears, the old Adam lives on, as can be told from a statement put out last week by the Peoples (*sic*) Business Commission, a pressure group in the Nader mould and based in Washington.

The latest declaration from 1346 Connecticut Avenue is, however, such a travesty of the truth that it deserves to be even more widely known than to those on the commission's mailing list. On Wednesday last week, the *New York Times* carried an account of how Dr Francis H. Ruddle and his colleagues at Yale University have been able to incorporate adenovirus and SV-40 genes into the DNA of mouse embryos. The newspaper quite properly quoted the investigators as saying that they had been able to demonstrate the presence of viral genes in somatic cells of mice developed from the manipulated embryos, but emphasizing that they knew nothing as yet of the physiological function (if any) of the genes concerned. They also pointed out that they have not been able to check whether the exogenous genes survive from one generation to the next, but that they hope to do so when their mice are sexually mature. The occasion for the appearance of this newspaper report was the imminence of a meeting in Berlin at which the work will be described; it is said to be due for publication in the journal *Cell*.

Plainly, last Wednesday was a black day at the Peoples Business Commission. The statement issued later in the week says that the report "marks the beginning of a eugenics program for America". Messrs Jeremy Rifkin and Dan Smith, described as directors of the commission, say that the development represents "the greatest potential technological threat to the sanctity of life since the beginning of human history". The statement goes on to say that "a few people and institutions now have it within their power to irreversibly alter the biological structure of millions of other men and women and their descendants for all time".

Many will say that foolishness of such a plainly exaggerated form is best ignored. That is too tolerant a view. For small though its direct influence may be, the Peoples Business Commission is well placed to help keep the pot of anxiety about genetic manipulation boiling unnecessarily. It should therefore be widely known that the commission's statement is, put simply, a misstatement of the truth, born possibly of ignorance. For Rifkin and Smith, diligent readers of the *New York Times* though they may be, do not read the scientific literature as carefully. For then they would know that the phenomenon in which endogenous virus genes are naturally incorporated into mammalian genomes is now familiar, and biologically important; that techniques similar to those attributed to Ruddle *et al.* have previously been used with other viruses (and not always in the United States); and that the investigation of this phenomenon may be of the utmost importance in the understanding of diseases such as leukaemia. No doubt the time will come when the *New York Times* reports the incorporation of a human gene into a human genome, but even when that happens it will be hard to justify such an intemperate statement as that put out last week. Is it not high time that the commission's sponsors, whatever their sympathies, found a more level-headed vehicle for prosecuting the case against genetic manipulation?

0028-0836/80/370096-02$01.00

NSF reorganizes for industrial research

Washington

The great White House hope that scientific research can be harnessed to the cause of industrial innovation has evoked a quick response elsewhere in the United States government. Other agencies are understandably keen to share in the action. At the National Science Foundation, the most immediate result will be to precipitate the reorganisation over which the National Science Board has been agonizing for several months.

Reorganization will dominate the agenda for a public meeting between the acting director of the Foundation, Dr Donald N. Langenberg, some members of the National Science Board, and the chairmen of the foundation's advisory committees which has been arranged for Saturday this week (13 September). The meeting will be open to members of the public, who will be able to chip in.

The National Science Board is hoping to have completed these and other consultations in time to make a final decision at its meeting in October. Failure to do so would mean that the proposed reorganization could not be built into the federal budget cycle, which might mean that some changes could not be carried out until October 1982.

The most obvious effect of the proposed reorganization will be to rename the Directorate of Engineering and Applied Science the Directorate of Engineering. More than nomenclature is involved, however — it is intended that each of the existing directorates of the NSF should be more directly concerned with the needs of applied science, while the new Engineering Directorate should vigorously support engineering research in universities.

Novel and explicit mechanisms for fostering industrial innovation are thus not a part of the proposed reorganization. Rather, the NSF is relying on the authority it already has to support industrial research. The scheme for funding joint industry–university projects is doing well. The NSF is also proud of the cooperative research centre in polymer science established at Massachusetts Institute of Technology (and now entirely supported by industrial companies). The analogous research centre for the furniture industry in North Carolina has been less successful.

These proposals are likely to win support. There will be more dispute about the proposal, part of the same package, to set up a Social Science Directorate even though the chief effect would be a repackaging of existing divisions (including the new programme in "decision and management" science). One objection is almost certain to be that "neural sciences", linked with "behavioural science", should not be separated from the rest of biology.

Under the new scheme, the foundation's existing rag-bag directorate (for Scientific, Technological and International Affairs) would take over responsibility for programmes such as those for supporting small business research and affirmative action of various kinds.

By Saturday's meeting, NSF will no doubt have been spurred on by Congressman George Brown's congressional subcommittee, to which Dr Lewis Branscombe (Chairman of the National Science Board) and Dr Langenberg are due to give evidence. Mr Brown is using his bill to set up a National Technology Foundation (unlikely ever to become law) as a way of urging on everybody in sight the importance of research as a spur to industrial innovation and production.

Meanwhile, the Department of Commerce has stolen a march on other potential competitors for the new funds that may become available in January by announcing its plans to set up three cooperative industrial research centres dealing with welding, lubrication and powdered metal processing. The Department of Commerce will spend $5.2 million of its own money on the projects, for which proposals are being sought, and hopes that its own contributions to the cost of the centres will shrink to 20 per cent after five years.

Appointments and elections ahead

Washington

After several nail-biting weeks, it now seems that the US Senate will confirm the nomination of Dr John B. Slaughter as Director of the National Science Foundation some time during the week beginning 15 September. It is now thought that the differences, political and procedural, which have arisen over Dr Slaughter's nomination as NSF director (originally announced early in July), will be found to have melted away (or to have been buried) at a meeting of the Senate Committee on Labor and Human Resources due to be held tomorrow, 12 September.

The first stumbling block to Dr Slaughter's confirmation was ironically the reinvocation by Republicans in the Senate of a principle first mentioned by Democrats in the closing months of the first Nixon Administration in 1972 – the doctrine that fixed-term presidential appointments should not be confirmed as soon as this before a presidential election.

Formally, the directorship of the NSF is a six-year appointment, although the statutes allow the President to remove a director from office at any time. In practice, however, a president following such a course would have to contend with the scientific community's view that the directorship of the NSF is not a political appointment in the ordinary sense. Dr Slaughter, when his appointment is confirmed, will be especially hard to dislodge, for he would be the first black American to head an important agency.

Technically, Dr Slaughter's confirmation as NSF director awaits only the vote of the US Senate as a whole, having been recommended ("reported out") by Senator Edward Kennedy's subcommittee on Health and Scientific Research. In practice, the recommendation is flawed by the way in which Democratic members of the subcommittee carried it without a proper quorum. Nobody wants the issue to be debated by the Senate as a whole. The emollient now discovered is a full meeting of the Committee on Labor and Human Relations at which Dr Slaughter's nomination will be on the agenda but (it is hoped) not discussed. The White House has no doubt been reminded of the quip, usually an ethnic slur, "with friends like that, who needs enemies?".

Dr Slaughter's problems (and the NSF's) may melt away, but Dr Al Carnesale, the putative chairman of the Nuclear Regulatory Commission, is certain to have a rougher ride. Carnesale's nomination, the confirmation of which is in the gift of a subcommittee of the Senate Committee on Environment and Public Works, is frankly acknowledged to be political, and for a specific reason. Carnesale, now a tenured professor at the Kennedy Institute at Harvard University, is committed to the view that breeder reactors are economically irrelevant while the price of uranium is as low as at present. Mr Ronald Reagan, the Republican presidential candidate, disagrees. The chances are that in the circumstances Dr Carnesale will have to bide his time until after the election.

Speculation about other post-election changes is already rife, and the odds are shortening on the proposition that Dr Frank Press, now the President's Science Advisor and Director of the Office of Science and Technology Policy, will finish up next spring as president of the National Academy of Sciences. A spokesman of the NAS confirmed last week that Dr Press is a "leading candidate" to succeed Dr Philip Handler, whose second six-year term ends next June.

Procedurally, however, there is a long way to go before this appointment will be decided. Proposals by the nominating committee have to be approved by the Council of the Academy in October.

The by-laws of the academy require that the nominating committee should "assure itself that each proposed nominee will be

0028-0836/80/370097-02$01.00

willing and able to serve if elected", which presumably implies a detailed discussion of the terms on which a "proposed nominee" would take the job.

Thereafter the council of the academy will inform the members, who have until 1 December to make alternative nominations (which must be supported by at least fifty members' signatures). If necessary, ballot papers are distributed by 15 December and must be returned by 15 January 1981. In principle, the council can put more than one name to the membership, but it has not in recent years done so. The present procedure, devised only in the 1960s, appears in the 1980s to be calculated to maximize the embarrassment of the "proposed nominee" and of the academy as a whole.

Bell Research Labs

Split possible?

Washington

There is much consternation at the Bell Telephone Laboratories at the unexpected announcement last week that the parent company, American Telephone and Telegraph (AT&T), is to split into two quite separate operating companies. This move, which has been prompted by a decision of the Federal Communications Commission (FCC) made public in May, may be followed at some later stage by a decision that Bell Labs itself should be split in two.

Scientists working at Bell Labs fear that such a development would impair the quality of the organization's research. For the time being, however, uncertainty rather than anxiety rules. No decision has been made as yet about the consequences of the split in the parent company for the research organization.

The crucial decision of the FCC (known as the Final Decision on the Second Computer Inquiry) is the latest stage in the FCC's decade-long attempt to adjust the rules for regulating the public telephone networks to meet new technical needs. Since 1968, the FCC has held that companies such as AT&T should not enjoy the exclusive right to supply terminal equipment for their telephone lines and other channels of communication.

More recently, the difficulties of regulating the common carrier networks have increased with the development of data processing networks, domestic satellite communications and the prospect of other technical developments. For the past four years, the FCC has been searching for a definition that would allow the networks to supply some kinds of equipment but prohibit them from supplying other items.

In its latest ruling, the commission has abandoned this exercise in semantics and opted for a more radical solution. In future, it says, large common carriers of electronic signals must be concerned only with the development and management of the network. If they wish to supply terminal equipment as well, they must do so through a separately constituted company with a distinctive board of directors, separate premises and so on.

Although the same rule would apply in principle to all telephone companies in the United States, for the time being the FCC has ruled that it should apply only to AT&T and to General Telephone and Electronics, which operates some 8 per cent of the American telephone network in locations scattered from Florida to California.

The response of AT&T to this radical proposal has been equally surprising. Although the company argued strongly against separation in its evidence to the FCC, on the grounds that vertical integration is beneficial, it announced last week that it would go ahead with the formation of two separate companies to be responsible respectively for the operation of the telephone network and the supply of terminal equipment (telephones included).

It is not yet clear whether the separation of the two parts of AT&T will be as complete as the FCC requires. Moreover, the move does not imply that AT&T accepts the commission's ruling — indeed, AT&T is one of thirty objectors who are threatening to carry their case to the courts if the decision is not modified.

The complication for Bell Labs is that the research organization is a jointly owned subsidiary of AT&T and of Western Electric, itself the subsidiary of AT&T responsible for manufacturing terminal and network equipment. The FCC ruling is vague on the implications of the proposed split in AT&T for research and development, saying only that affiliated companies would be required in future to buy research and development services from other affiliated companies at a fair valuation.

One obvious development, that most feared at Bell Labs, is that AT&T may in the end be required to divide both Western Electric and Bell Labs itself into parts separately responsible for communications networks and for terminal equipment. AT&T is also alarmed at the prospect that even separation of activities on which it has now embarked will impede the free flow of ideas between operations and research and development.

If there were to be a split of Bell Labs, the chances are that the largest part would go to the network side. Of the 1980 budget of $1,255 million, more than 45 per cent was exclusively concerned with network operations. The remainder may be considered relevant to both sides of the telecommunications business.

How soon the future of AT&T and of Bell Labs will be decided is a matter for conjecture. The FCC has set a deadline for the complete separation of AT&T by March 1982, but will now be required to comment on the objections to its ruling, most probably in October or soon afterwards. If the courts accept that the objectors to the ruling have a case, several further months may elapse before the regulations have the force of law, in which case the deadline would no doubt be put back. Excessive delay is likely, however, to breathe life into the bills now languishing in Congress that aim more directly to regulate the public communications networks.

NPT review conference

No declaration

The Second Review Conference of the Non-Proliferation Treaty ended on Sunday (two days later than originally planned) with a smack in the face for the three sponsoring nuclear powers, the Soviet Union, the United Kingdom and the United States. Although the nuclear powers had been expecting trouble at the conference, largely on the grounds that they had been less diligent than required by the treaty in the pursuit of strategic disarmament and the fostering of civil nuclear developments elsewhere in the world, they were apparently taken aback also to find themselves criticized on the grounds that either Israel (not a signatory of the treaty) or West Germany (which is) had been helping with the development of nuclear weapons in South Africa.

The most immediate cause of trouble was the failure of the conference to agree on a report of the past month's proceedings at Geneva. The drafting process came to a fruitless end in the early hours of Sunday morning, and the conference was concluded later in its day.

By all accounts, the review conference has been rought going ever since the opening speeches were made in public during the first ten days. The government of Mexico appears to have taken the lead in asking that the nuclear powers should agree to a package of demands on arms control, including a declaration that they would abide by Salt II while awaiting ratification of that treaty, impose on themselves a moratorium on nuclear testing and allow the negotiations on the Comprehensive Test-Ban Treaty (conducted up to now between the three nuclear power signatories of the treaty) to be carried on with the UN Committee on Disarmament. For the nuclear powers, the sticking-point last weekend was this demand that such a declaration should be included in the final report of the review conference.

The overriding question now is whether the failure to produce an agreed report will be followed by mass defections from the treaty. The closing speeches at Geneva, including that from the Iraqi chairman, were variations on the theme that nuclear proliferation remains a serious danger, and that the conference had served to draw attention to many of the beneficial aspects of the treaty.

The discovery by several of the

0028-0836/80/370098-02$01.00

signatories that the quinquennial review conferences offer a means of twisting the arms of the nuclear powers on arms control may paradoxically help to keep some states loyal to the treaty. Others, however, will no doubt be able to use the failure to produce an agreed report as an excuse for withdrawing from the treaty, even though those tempted to take such a step will no doubt be impelled in that direction by separate political considerations.

In the wake of the Geneva conference, the meeting of the Committee on Assurances of Supply of the International Atomic Energy Agency, planned for the end of this month at Vienna, assumes greater importance. It is thought unlikely that the nuclear powers will be spurred to further negotiations on strategic disarmament at least until after the American presidential election.

Plutonium

Dounreay loss

Only a few weeks before the British government is due to make an announcement on the future of the fast breeder reactor, the BBC television programme *Panorama* alleged on 8 September that a total of 35 gram of plutonium from the prototype fast reactor at Dounreay was lost in 1973 and 1976. The United Kingdom Atomic Energy Authority admits that the plutonium has never been accounted for, but says that it could not have left the fuel cycle and was most probably reprocessed or even dumped in a waste repository.

The first case of missing plutonium occurred in 1973 when a routine accountancy check revealed that 10 gram of the element was missing from a can containing the remnants of several spent fuel pins. The pins, originally about 0.2 inches in diameter and 2 feet long, had been irradiated in the reactor core for one year and then chopped up for analysis by chemists and metallurgists. The shortfall in plutonium was equivalent to one fuel pin.

The second case concerned a fuel pin which had been irradiated in the reactor core for one day in 1966. It had then been treated in the same way as the first pin and the can containing it had been stored in a cooling pond. It contained 25 gram of plutonium. In 1977, the can that was thought to contain the remains of the fuel pin was found to contain another type of spent fuel.

The UKAEA says that it investigated the losses and reported the second to Euratom, of which Britain was then a member. A driver of a mechanical digger was hired to uncover all the material in a dump of low-activity waste in the hope that the second lot of missing plutonium would be discovered. The contents of the dump were analysed, but the missing spent fuel was not found.

The UKAEA says that each case was investigated thoroughly, and that the to missing irradiated fuel pins must either have been reprocessed or dumped in a depository for highly radioactive wastes, examination of which would be too hazardous to undertake. It says the plutonium could not have been removed from the fuel cycle. Its conclusion is that there must have been an error in the system of keeping records of the movement of plutonium. Since the incidents, the UKAEA says, it has tightened up on its procedures for monitoring the movement of radioactive materials around the plant.

The *Panorama* programme was also critical of operations at Dounreay on health and safety grounds. It claims that the driver of the mechanical digger, a deaf-mute, was not properly aware of the hazards of what he was doing and was not given adequate protective clothing. It also cites another incident in 1979 when eight men were exposed to plutonium after handling radioactive waste. None of them was aware that the waste contained plutonium and at the end of their shift it was discovered that they had been exposed to radiation.

About this incident, the UKAEA says that the waste handled by the men contained only one gram of plutonium and that none of the men was later found to have significant amounts of plutonium in his blood or urine. The incident had not been reported because the level of alpha radiation in the air in which the men were working was well below the level at which notification to the authorites is obligatory. An attempt was made, says the UKAEA, to inform the deaf-mute driver of the hazards of what he was doing. He was told to stay in his cab and air samples were monitored for radiation. The levels found were within the safety limits.

The uncovering of the incidents has provoked a strong reaction from Mr David Steel, leader of the Liberal Party, who has called for a ministerial statement on the affair. Even before the showing of the film, the AEA had issued a statement that *Panorama* had exaggerated the significance of these incidents, and had also charged the BBC with having declared an interest in making a film about this achivements

Academic freedom

Talking shops

The Hague

Three papers by Dr Andrei Sakharov, written since his exile to Gor'kii, *Eksperimental'noi i Teoreticheskoi Fiziki* (*ZhETF*), the most prestigious physics journal in the Soviet Union. This remarkable development was announced by Nobel Laureate Philip Anderson to last week's Conference of the International Sakharov Tribunal of Conscience and Peace.

According to Professor Anderson, the Editor of the *ZhETF* had initially accepted the papers, which deal respectively with time-reversal, quark/gluon interaction and mass formulae for muons and baryons. At a late stage, however, the censors stepped in to stop publication. The matter, said Professor Anderson, was finally "adjudicated" by the Central Committee of the Politbureau, who decided that publication could go ahead.

The story which amplified by Professor Edward Lozansky, Chairman of the International Sakharov Committee, New York, and a former member of the Moscow Sunday Seminar for Jewish "refusnik" scientists. He told the conference how he had brought the three Sakharov papers to the meeting of the American Physical Society (APS) in April, which decided that if the papers were turned down for political reasons by the Soviet journals the APS would be delighted to consider them. This, thought Lozansky, had probably swung the balance in Sakharov's favour.

Ironically, this revelation of how much Western academic pressure can achieve on behalf of a harassed Soviet colleague was announced at a conference which, in the opinion of several campaigners for academic freedom, should not be taking place at all. One of these is Mrs Tamara Yankielevich, Sakharov's stepdaughter-in-law, now resident in the United States. The main grounds for opposing the conference have been the veiled hints from the Soviet side that vociferous action might jeopardize a plan to allow Sakharov quietly to return to Moscow. "Six months after being exiled" was the first date promised for his return; this has now however become "six months after the end of the Olympics".

Unlike the various other "Sakharov" human rights conferences in the past few years, the Hague conference was a human rights conference specifically focused on Sakharov's own plight. As several speakers pointed out, this is a relatively mild plight. For example, Sakharov still has access to a scientific library just across the street from his Gor'kii apartment. Because all the scientific institutes in Gor'kii are involved in classified work, however, there is no possibility of his having any contact with fellow scientists in his place of banishment.

In his presentation to the conference, Professor John Ziman of the University of Bristol suggested that one of the reasons scientists are particularly concerned with Sakharov's case is that his involvement with problems of academic freedom and human rights generally grew out of his disillusionment with a career in nuclear weaponry — what Ziman called "black science" — like black magic, "the application of knowledge in the power of evil".

His "pilgrimage", as Ziman called it, is therefore of particular concern to all scientists, "hard put to it these days to defend our traditional norms — the universality, the disinterestedness, the openness of a transnational community bringing beneficial knowledge to all".

0028-0836/80/370099-02$01.00

Coincidentally with the Hague conference, two other meetings concerned with the political repression of scientists also took place last week. In Amsterdam, there was the annual meeting of the International Council of Scientific Unions (ICSU) and of its specialist committees, including the Committees on the Free Circulation of Scientists and Safeguards of the Pursuit of Science. This committee, which compiles a register of cases of scientists subjected to unwarranted restriction, is less well known than it should be. During the past year, only some seventeen such cases were added to the register.

The particular roles of scientific and learned societies were stressed at the other meeting last week — the half-day session on scholarly freedom and human rights at the Salford meeting of the British Association.

Marks of reproof

What follows is a summary of Dr Leslie Cohen's suggestions as to how learned societies may help colleagues elsewhere whose academic freedom or human rights are restricted (see text).

1. Statement by the President of the Society.
2. Formal protest by Officers of the Society (published in the Society's bulletin).
3. Provision of facilities for protest meetings, press conferences.
4. Official letter of protest to head of State Party/Academy.
5. Dissemination of information on individual cases to members.
6. Advising members to refuse to
   (a) attend meetings in offending country;
   (b) invite scientists from offending country to conferences;
   (c) allow visits of scientists from offending country, to scientific establishments/laboratories;
   (Note in special cases, visits may be made contingent on discussion of human rights issue in question).
7. Organization of petitions by members on specific case.
8. Granting of recognition and/or publicity to "alternative" meetings and seminars organized by banned scientists.
9. Organizing and/or supporting meetings relating to the work of one particular scientist suffering repression.
10. Sending delegation to investigate cases and intervene if possible.
11. Providing journals free to banned scientists.
12. Providing financial support to exiled scientists.
13. Severing formal relations with academies/societies in offending countries.
14. Causing expulsion of academies/societies of offending country from international organizations.

At such conferences, the question of how to translate concern into concrete action is usually answered only vaguely. On this occasion, Dr Louis Cohen, secretary of the Physical Society (London), put forward a fourteen-point scheme of progressively more severe responses that learned societies might make (see below).

By way of demonstrating what may be achieved by pressure from professional colleagues, Professor John Charap of Queen Mary College, London, was able to announce at the BA meeting an unprecedented success in the case of Yurii Gol'fand, his fellow researcher on supersymmetry. Gol'fand, who was dismissed some years ago from his post as senior researcher at the Lebedev Institute of Physics in Moscow following his application to emigrate to Israel, was, a few weeks ago, reinstated.

Hoyle on life

No dissent

It would be hard to imagine an event more like that of Daniel entering the lion's den than last week when Sir Fred Hoyle, brandishing his theory that influenza epidemics are caused by extraterrestrial viral material, gave a seminar at the National Institute for Biological Standards and Controls in Hampstead, London. In the event, Sir Fred escaped almost as unscathed as Daniel, although perhaps for different reasons.

Hoyle has evolved his theory in conjunction with Professor N.C. Wickramasinghe of University College, Cardiff, with whom he has recently collaborated on a series of papers on the occurrence of biochemicals in intersteller space. The theory that viruses might also be present in space is a natural extension of that line of work. It is worth postulating, according to Hoyle, because of some anomalies in the epidemiology of influenza which defy the conventional explanation that the virus is passed from person to person, with animals acting as a reservoir.

The anomalies to which Hoyle points are few but striking. He cites, for example, outbreaks of influenza in boarding schools where the great majority of cases occur simultaneously quite unlike the expected, progressive spread from one or a few initial cases. More strikingly he points to reports of the simultaneous outbreak of influenza in the USA and India during the 1918 pandemic. What better explanation for such phenomena than that a space-borne factor descends to trigger the influenza in all cases at the same time? And, in support of that notion, Hoyle marshalls plenty of evidence of atmospheric events that could account for the odd incidence of influenza.

A version of Hoyle and Wickramasinghe's theory that has been circulating in preprint form proposed that individuals carry as part of their own genes the genetic information for each of the many types of influenza virus and that there was a separate space-derived, activating factor for each.

Now, however, he is persuaded that this version of the theory is inadequate in part because of overlooked evidence and in part because biological systems have a good deal more slack than he, as a physicist, had been aware of. As a result the theory has become more complex and now involves a coincidence of three virus-related components, two of them space-derived, for infection to occur.

In becoming so complex, the credibility of the theory has undoubtedly been stretched more than ever. There is also the question of whether or not the basis of the theory — the anomalous epidemiology — is sound. Thus in the discussion that followed Hoyle's talk, Dr A. J. Smith of the Influenza Research Unit at St Luke's Hospital, Guildford, outlined his unit's study of the spread of influenza in a school. Unlike the evidence cited by Hoyle, Smith's data fitted the classical progressive spread of the disease, from a single person, to all those who finally succumbed.

That, however, was the only criticism of substance put to Hoyle in the discussion period. One respected influenza expert was prepared to venture the view in private that whereas he and others had no time for Hoyle's theory they were too polite to say so; "in the USA he would have been eaten alive".

And so it came to pass that, for reasons perhaps more British than biblical, Sir Fred survived the tame lions of Hampstead.

Peter Newmark

Electric vehicles

UK content

Government and industrial support for British research and development on electric vehicles should continue at its present level even though it is likely to be many years before electric vehicles become commercially viable. This is the main recommendation of the first report of the House of Lords Select Committee on Science and Technology, published last week.

The technical problems of developing advanced batteries suitable for use in private cars and of building an infrastructure for overnight recharging are identified as the main obstacles to the early success of the all-electric car. Another problem is that most of the advantages accrue to society and the electricity generating industry and most of their disadvantages fall on their owners. Their commercial success is therefore unlikely much before the petrol-run car becomes exceedingly expensive to run, probably towards the end of the century.

0028-0836/80/370100-02$01.00

The Lords committee warns that there is a danger of Britain becoming complacent about the need to develop alternatives to the internal combustion engine because the availability of North Sea oil might make petrol-run cars economic in Britain after they have ceased to be so in other countries. The committee recommends that the government encourage electric vehicle manufacturers to continue their research at least at the present level, which it finds satisfactory, by continuing to give financial support matched in some way to the manufacturers' own investment. Government should also be prepared to make product-launch money available "to get over the volume-production lump in the next few years". The committee does not, however, suggest that electric vehicle research be centrally planned, finding the present system of manufacturers applying for grants on an *ad hoc* basis satisfactory. It has seen no evidence of any overlap of research.

There is one area, however, in which the Lords say that more work could be done. Hybrid vehicles, propelled by a combination of battery and internal combustion engine, are being vigorously explored in Japan and the USA, but have so far received little attention in Britain. They offer the most promising prospects for private use by overcoming the pure electric car problem of short range, typically 50-70 miles. They also do not necessarily depend on the development of new advanced batteries. A major disadvantage, leading to high capital cost, is that incorporating two different propulsion systems in one vehicle is technically very difficult. Nevertheless, the government should be prepared to make a "small" amount of public money available for testing them, says the committee.

The future of electric vehicle development lies with large companies prepared and able to invest heavily in research and development and not with small businesses set up to build one or two specialized vehicles, says the report. So far, the manufacturers of batteries and components, such as Lucas and Chloride, have invested much more than the major car manufacturers. A possible reason, put to the committee by BL Technology, a subsidiary of British Leyland, is that vehicle manufacturers add only 30 per cent of the final value of an electric vehicle, the electrical component manufacturers standing to win the biggest reward.

The committee hopes that the car manufacturers will eventually be enticed to invest in electric vehicle development by the prospect of major markets in countries which, unlike Britain, cannot rely on a steady supply of oil into the 1990s. It would be a pity, it says, if Britain were to lose its lead in electric vehicle technology now, only to be forced later into buying from abroad because it had been lulled into a false sense of security in the 1980s.

US petroleum

Using less

Washington

Officials at the Department of Energy appear to share with the superstitious the view that to talk about good luck is to ensure that it will disappear — "don't count your blessings" and all that. Accordingly, not much is being made of the dramatic reduction of crude oil imports to the United States in the past year, which in the first eight months are down by 17.2 per cent between 1979 and 1980.

According to the Department of Energy's *Weekly Petroleum Status Report* for 29 August, imports of crude oil and refined products averaged 6,907 million barrels a day in the first 234 days of 1980, compared with a total of 8,341 million barrels a day in 1979. If this keeps up, President Carter's promises at the Venice summit on oil imports will be amply fulfilled.

The diffidence of the statisticians responsible for the weekly statistics is partly technical. The weekly *Status Report,* although admirably up to date, is based on returns from oil companies and crude oil refiners, and is therefore not a direct measure of actual consumption. Perhaps, it is said, the reduction of imports reflects reduced inventories in the distribution network. The rapid attritition of gasoline service stations certainly implies that many retailers' gasoline tanks have been emptied for the last time. The statisticians appear not to dare to take heart from the supposition that most retailers going out of business are doing so because they are selling less.

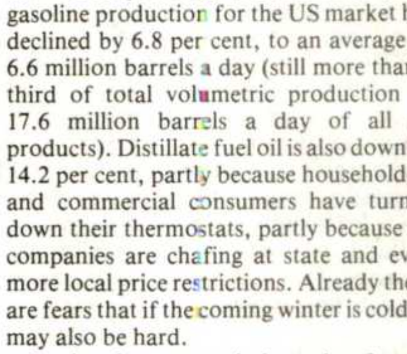
The statisticians are also diffident because they do not understand why the most recent round of price increases for petroleum products should have demonstrated, after a decade of apparent price inelasticity, that even Americans will buy less gasoline and fuel oil if the price goes up sufficiently. Could it even be that some non-quantifiable consideration, such as the continued presence of American hostages in Iran, has changed people's buying habits?

Whatever the truth, the facts are clear. Between the first eight months of 1979 and the corresponding period this year, gasoline production for the US market has declined by 6.8 per cent, to an average of 6.6 million barrels a day (still more than a third of total volumetric production of 17.6 million barrels a day of all oil products). Distillate fuel oil is also down by 14.2 per cent, partly because householders and commercial consumers have turned down their thermostats, partly because oil companies are chafing at state and even more local price restrictions. Already there are fears that if the coming winter is cold, it may also be hard.

During the same period, stocks of crude oil and of petroleum products have soared. Primary commercial stocks have increased by more than ten per cent in the past year. Gasoline is in especially good supply. Fuel oil is, however, short.

The most obvious disappointment in the statistics so far available for 1980 is that US oil production has hardly changed since

Saturn seen in Voyager sights



Saturn from Voyager 1 on 24 August, 1980. The dark band on the equator is the shadow of this rings. The three bright specks are satellites.

The accompanying photograph, released at the end of August from the Jet Propulsion Laboratory in California, is one of the first to have been gathered from the spacecraft Voyager 1, now on its way from Jupiter to Saturn. Between 22 August, when the first photographs were obtained, and 24 October, visual observation from Voyager 1 will consist entirely of single-frame photographs. Thereafter, the narrow-angle camera on the spacecraft will be used to collect mosaic photographs of the visible surface of Saturn and of the rings and to search for satellites at present unknown.

The closest approach to Saturn will occur on 12 November, when the spacecraft will also come closest to the satellites Tethys, Mimas and Enceladus. The closest approach to Titan, one of the principal targets for the cameras, will occur on 11 November. Visual observation of Saturn will continue at least until 18 November.

Visual observations are, of course, merely the most memorable of the observations made by planetary spacecraft. Voyager 1 is also equipped with magnetometers, infrared sensors (which will, in particular, produce a map of the surface of Saturn) and devices for recording the interplanetary particle flux and for measuring the size and density of material particles in the rings of Saturn.

0028-0836/80/370101-02$01.00

1979, increasing by only 2 per cent. One explanation of this curious price insensitivity is that potential oil producers are waiting until the price of "new" oil is decontrolled towards the second half of 1981.

The economic consequences of this changing pattern of consumption are plain to see. The three major automobile manufacturers are in the throes of launching their newest small cars — Ford unveiled its new Escort last week — with apprehension and despondency. It the cars do not sell, consumers will buy imported cars and the auto industry will collapse still further. But the profitability of small cars is not nearly as great as that of the old gas-guzzlers.

Using the standard relationship but on the assumption that coal production will continue rapidly to increase, the American Petroleum Institute is now guessing that by 1990 oil consumption in the United States will decline to an average 8-9 million barrels a day, with rather less than half of this imported. Even this estimate may be conservative, for the impending decontrol of petroleum prices may be an unexpected stimulus to drilling. Since the decontrol of natural gas prices during 1979, proven reserves of natural gas have increased more quickly than in the previous decade.

Romanian energy

Partners to-be

Romanian President Nicolae Ceausescu has found the answer to current and future problems of the development, efficient and economic use of raw materials and energy resources, according to the leading Party newspaper *Scinteia.* Reviewing the latest volume in the series "From the Economic Thinking of President Nicolae Ceausescu", *Scinteia* points out that the President was interested in the problem even before the energy crisis. This is, perhaps, not surprising as Romania, once so oil-rich that an oil-rig was depicted on the state coat of arms, has now sunk to the status of a net oil importer.

Judging from the review Ceausescu's book *Energy and Raw Materials Resources* (not yet available in the West) seems to reiterate the draft directives for the 1981–85 five-year plan and the long-term guidelines till 1990, recently accepted by the Joint Plenary Meeting of the Central Committee of the Romanian Communist Party and the Supreme Council of Economic and Social Development.

These guidelines provide for a multilateral energy strategy, to include: the expansion of geological prospecting throughout the country and the Black Sea continental shelf, the speeding up of hydroelectric projects, so that the 30 per cent exploitation of hydroelectric potential of 1980 will reach 45 per cent in 1985, 65 per cent in 1990 and 100 per cent in the year 2000, utilization of low grade and less accessible fuels such as shale, and the expansion of the nuclear energy programme (660 MW capacity by 1985, 3,960 MW by 1990 and 10,000 MW by 2000).

Considerable emphasis is also to be placed on conservation, recycling and what looks remarkably like energy rationing — described by official policy hand-outs as "fixing rational ceilings on heating and lighting". Finally, Romanian scientists, whose work has been more firmly harnessed to the needs of the economy than in any other socialist country, will take part in wide-ranging interdisciplinary research to capitalize on the country's geothermal, Sun, wind and tidal resources, as well as biomass conversion. According to the directives, by the year 2000 these resources should account for some 20 per cent of Romania's energy production (by then nuclear energy will have reached 17 per cent).

Vera Rich

Rural communities

Living now

What sort of society could the future inhabitants of rural areas find themselves living in? A recent idea for a rural community for the future has come from the Dartington Hall Trust in South Devon, England in the form of a model village built on a scale of 1:250. Recognizing, no doubt, that the future can never be planned by the past, the Dartington model has been designed more as an "exercise in the imagination" than as a blueprint for a real village.

Thinking about the future of rural communities fits well into the work of the Dartington Trust, which was set up in the 1920s with the wealth of Leonard and Dorothy Elmhirst to bring back life to rural communities which has been depleted during the industrialization of the nineteenth and twentieth centuries. Most of Dartington's work consists of encouraging small industries, not necessarily associated with rural life, and cultural and educational activities in the countryside of Devon. Its latest venture, however, is more theoretical. According to Maurice Ash, the Trust's chairman, the model village is an attempt to "speak a new language" by thinking differently about the world in terms of qualities rather than quantities.

Dream in balsa wood

That is not to say, however, that the "high" technology of the industrialized world has been ignored. The idea, according to Andrew Page, the brains behind the model, is to achieve a marriage of the microelectronics and green (ecological) revolutions. The model is for a community of about 2,000 people which aims to be as self-sufficient as possible by making use of both "low" and "high" technologies, the emphasis being on energy saving and preserving the quality of the environment. Electricity is supplied mainly from hydro and aerogenerators, transport within the village is by bicycle, horse and cart or on foot, as much local produce as possible is grown around the periphery of the village using labour intensive methods and waste recycling is done on site to produce clean water supplies and methane and other biogases. The village medical centre is designed to offer "alternative therapies" as well as modern medicine.

High-technology services come into their own when the village has to communicate with the rest of the world. Hence a community transport depot houses cars, lorries and vans for those needing to travel outside the village. But the most significant feature is the "cottage office" which houses a "resource centre" offering not only telephones, telexes, photocopying machines and secretarial and accounting services for local businesses, but also television with teletext, Viewdata and other link-up services for worldwide electronic communication. This acknowledgement of the microelectronics age also means that the village can offer educational facilities for all age groups.

Small-scale industry, for producing goods for sale outside the community as well as within it, is based on a mixture of high and low technologies. Few inhabitants would have only one job, the idea being to create job fulfilment by blurring the distinction between work and leisure and engaging people in different tasks at different times. Most people, for example, would spend quite a bit of time farming the green belt surrounding the village or digging their allotments, in addition to their main job. One of the main criteria for using high, labour-saving technology would be the elimination of boring and repetitive tasks.

It is unlikely that the model village will ever become a reality. But some of the ideas and detailed design work that have gone into creating it may be useful in less ambitious projects to build real futuristic societies. The Town and Country Planning Association and Greentown Group, for example, are currently looking for a site to build a small futuristic community of houses and small businesses. And Milton Keynes has already shown an interest in building such a community on a 25 acre site just outside the town. **Judy Redfearn**

0028-0836/80/370101-02$01.00

NEWS AND VIEWS

The elementary Universe

from M.G. Edmunds

SINCE nearly every object in the Universe contains more than one chemical element, it is perhaps not surprising that the experimental determination and theoretical explanation of the abundances of the elements is a rich field of research. The relevance of abundance studies to the whole of astrophysics was very evident in this summer's Santa Cruz Workshop*.

The initial Big-Bang left only isotopes of the very lightest elements, and everything from carbon onwards must have been built up during the evolution of the Universe out of hydrogen inside stars. The synthesis of most elements has been assumed to occur by nuclear reaction chains in the extreme temperatures and densities which occur when a star explodes as a supernova. Although there was much indirect evidence for this basic assumption, it is only recently that direct observational evidence has been found. The analysis of the optical spectra of remnants from such explosions in our own Galaxy (the remnant Cas A) and from a remnant in an irregular galaxy (NGC 4449) by R.P. Kirshner (University of Michigan) does at last provide a clear demonstration that synthesis reactions have occured. The debris of the explosions can be seen streaming out at some thousands of kilometers per second, and has a composition dominated by freshly-synthesized heavy elements (particularly oxygen) with very little unprocessed hydrogen remaining.

Supernovae divide up into two main classes — Type I and Type II — on the basis of the way their phenomenal light emission fades in the first few months after explosion. The exact nature of the stars which give rise to the two different types remains uncertain, but Type II may originate from massive stars (perhaps larger than twelve solar masses). Type I might originate from single stars of somewhat lower masses, or (as originally suggested by J. Whelan & I. Iben *Astrophys. J.* **186**, 1007; 1973) from a binary system of stars when matter is transferred from one component of the system to the other, more condensed star. Models of this second kind were particularly popular at Santa Cruz. Both T. Weaver (Livermore Laboratory) and K. Nomoto (Goddard Space Flight Center) investigated a version in which the gradual transfer of helium onto a white dwarf star results in conditions which give a sudden detonation of nuclear reactions. The exponential pattern of the decay of light output from the resulting explosion gives a fairly direct indication of nuclear syntheses, since the energy output originates in the radioactive decay of freshly synthesised ^{56}Ni which decays to ^{56}Co in a few hours, and then to stable ^{56}Fe in a few months. Models presented by T. Axelrod (Livermore Laboratory) suggest that up to one solar mass of decaying nickel may be involved in a typical Type I supernova, and he claimed that spectral lines of ionised cobalt can be seen in the optical spectrum with a strength and time variation consistent with the decay of large amount of ^{56}Co.

Exactly how the supernovae explode, and how much of the parent star is neutronised and left behind as a highly condensed stellar remnant, remains uncertain — although everyone seemed to agree that the amount of rotation present is likely to be very important in determining the dynamics of the explosion. A particularly intriguing possibility is that, if the pre-supernova star sheds enough of its outer layers for non-explosive mass loss, then a nuclear runaway might occur without a violent release of optical radiation (although there would probably be copious X-ray emission). Thus it may be possible to form neutron stars without an obvious optical supernova event, although a recent lowering of the estimate of the birthrate of pulsars in the Galaxy to one every hundred years (M. Arnaud & R. Rothenflug *Astron. & Astrophys.* **87**, 196; 1980) indicates that optical supernovae may, in fact, provide sufficient neutron stars to account for the observed population.

Supernovae also provide one of the best means of establishing the distance scale to external galaxies, and D. Branch reported work by himself and others at the University of Texas on a supernova in the galaxy M100 which suggests a Hubble constant near 60 km s^{-1} Mpc^{-1}. The result was greeted with relief by many participants because some recent higher values had implied an age of the Universe much smaller than that estimated from radioactive isotope ratios and from ages of old star clusters suggested by stellar evolution theory.

The relative contribution of Types I and II supernovae to the overall heavy element abundances in the Universe is also uncertain, (see, for example, B.M. Tinsley *Astrophys. J.* **229**, 1046; 1979). The observation that oxygen seems more abundant relative to iron in very old stars (which are a sample of early Galactic history) than it is in young stars, prompted S. Woosley (Lick Observatory) to propose on the basis of nucleosynthesis calculations by himself and T. Weaver that oxygen is predominantly synthesised in Type II supernovae and that there were relatively more of these massive stars early on. The major source of iron in the Galaxy would then be subsequent Type I supernovae.

On a galactic scale, the existence of abundance gradients in our own and other large spiral galaxies appears to be well established, in the sense that the central regions have more heavy elements per unit mass than do the outer parts. The best indicators so far are the photoionised HII gas regions, whose spectra have been extensively observed by American, British, French and Mexican groups over the past few years. For our own Galaxy, dust extinction in the Galactic plane makes optical observation difficult, but P. Shaver

*The Santa Cruz Workshop in Astronomy and Astrophysics on "The Origin and Distribution of the Elements" was held from July 6 to July 18 at the University of California, Santa Cruz.

M.G. Edmunds is in the Department of Applied Mathematics and Astronomy, University College, Cardiff.

0028-0836/80/370103-02$01.00

(European Southern Observatory) presented radio recombination-line data which show a definite gradient in the electron temperatures of the gas regions as a function of their position in the Galaxy. This may be directly interpreted as an abundance gradient since the temperatures are largely determined by the cooling of the nebula by radiation from the heavy atoms — if abundances vary, then so will the temperatures. For other galaxies there is some indication that the gradients may be flatter in earlier Hubble types, but this correlation of gradient with morphology is unclear, particularly as M. McCall (University of Texas) presented evidence for very different gradients in two galaxies (M101, NGC 6946) which have been classified as exactly the same morphological type.

Even more problematic was P. Wannier's (Caltech) conclusion that the isotope rations ^{12}C/^{13}C, ^{16}O/^{18}O, ^{14}N/^{15}N (as accurately determined from radio molecular line spectra) do not vary significantly across the disk of our own Galaxy, except right in the Galactic Centre. This result is very surprising since the production and destruction rates for the rarer isotope of each of these pairs would be expected to vary considerably if there exists an overall abundance gradient across the Galaxy. Although there may remain some uncertainty in the correction of the molecular line data for fractionation effects in the clouds where the molecules are found, it seems that a radical re-think of the production mechanisms (particularly of ^{18}O, ^{15}N) may be required. Why the Galactic Centre should be different is anyone's guess, but M. Peimbert (University of Mexico), with his discovery of a small Seyfert-like nucleus in M81, reinforced the idea that perhaps all galactic nuclei in spirals are peculiarly active.

The peculiar variation in abundance ratios observed between different stars in some globular star clusters remains something of a mystery. Some of the variations can be ascribed to nuclear processing during the normal evolution of the stars, but variation in other elements seems to force acceptance of the view that there were considerable (and peculiarly selective) inhomogeneities in the initial composition of the gas cloud out of which the clusters formed. But even the anomalies explicable by nuclear processing are not well understood, because according to existing theory many of the stars have not reached a sufficiently advanced evolutionary stage for the products of nuclear reactions in the core of the star to be mixed up by mass motions and reach the surface where they are observed.

The possible inadequacy of mixing theory in stars was stressed by S.E. Persson (Mount Wilson Observatories) for the so-called 'carbon' stars in the Magellanic Clouds, where again there is clear evidence of nuclear processing and mixing at luminosities well below theoretical predictions. Evolved stars undergoing mixing are also a site for synthesis of elements which are formed by repeatedly capturing neutrons at a rate which will allow each successive product of the reaction to β-decay (if it is unstable) before the addition of another neutron. A rather nice demonstration of the occurrence of this reaction chain under different conditions was given by H.E. Bond (Louisiana State University) in his differentiation between 'classic' and 'marginal' Barium stars. In the 'classic' stars the flux of neutrons in the stellar interior has been high enough to add sufficient neutrons to the iron group elements (atomic number A $\sim$ 56) to synthesize considerably heavier elements, giving the characteristic observed over-abundance of Barium (A = 138). The 'marginal' stars show evidence of only a small amount of neutron addition, giving over-abundances of Strontium and Yttrium (A = 88, 89) but insufficient addition to build up a large excess of Barium. Here is concrete evidence of different amounts of nuclear processing during the normal life of stars.

The study of such systematic variations in abundances is of vital importance in sorting out the theory of mixing, and hence tightening up the (still very real) uncertainties in stellar evolution models.

Typical of the spin-off from abundance studies is the discovery by B. Carney (Carnegie Institution of Washington) that there exist some old stars near the Sun with space velocities very much in excess of the velocity of escape from the Galaxy which would be calculated on the assumption that the Sun is near the edge. The continued retention of such stars in the Galaxy strengthens the case for the existence of a large amount of unseen mass outside the Sun's Galactic radius.

The improvements in mass and charge resolution of cosmic ray experiments over the past few years are now beginning to bear fruit. After the observed fluxes have been corrected for reaction during the propagation from their source to Earth, there are no major differences between comic-ray heavy-element composition and that observed in the interstellar medium.

This suggests the origin of Galactic cosmic rays is accelerated interstellar material, rather than freshly-synthesized particles thrown out from the interior regions of a supernova explosion. With present resolutions, one anomaly does seem definite; this is the greater abundance of ^{22}Ne relative to ^{20}Ne in comparison to that observed in most solar system material. Numerous models were invented to explain this, but perhaps the most attractive was the suggestion (S.E. Woosley) that material which had undergone reactions involving the fusion of helium in stars (a product of which would be ^{22}Ne) is preferentially accelerated into cosmic rays. The acceleration would presumably act on this matter after it had been lost from the star. Both the cosmic-ray and gamma-ray observers were quick to point out the serious dilemma facing them — more statistics are needed, and their next generation detectors will have much superior capability, but the number of flights on which they can launch their equipment into orbit is dwindling rapidly.

Another aspect of this widely-ranging workshop was discussion of the isotopic anomalies found in certain discrete regions (or 'inclusions') in meteorites, the anomalies contrasting with a remakable uniformity of isotopic composition (apart from some well-understood fractionation effects) in most solar system material. The anomalies may result from large inhomogeneities in the isotopic composition of the early solar system nebula, although H. Norgaard (Niels Bohr Institute) outlined a scheme for synthesising ^{26}Al (which decays into ^{26}Mg, one of the principal anomalous isotopes) in red giant stars and hoped that dust condensing in the giant stars' atmospheres would provide suitable transport to the early solar system for the radioactive aluminium and its decay product. But the anomalies occur in many different elements, for example G. Wasserburg (Caltech) had found a huge 200% anomaly in ^{107}Ag/^{109}Ag. Confusion is added by the lack of some anomalies which would be expected on nuclear production explanations for other isotopes. Although much beautiful experimental work has been done in discovering these anomalies, their origin remains obscure and must rank as one of the major cosmochemical puzzles.

There was, however, at least one area in which good agreement was reached. This was an estimate of the pre-galactic (i.e. Big-Bang produced) helium abundance. Work by several groups (particularly Peimbert and his collaborators) based on the analysis of spectra of HII regions in irregular galaxies, gave a primordial helium mass fraction of $Y = 0.225 \pm 0.015$. This is in excellent agreement with an estimate of $Y = 0.23 \pm 0.01$ which V. Castellami (University of Rome) made for the helium abundance in a particular type of globular cluster which could be rather well constrained on the basis of stellar pulsation and evolution theory. Since the synthesis of helium in the Big-Bang is influenced by the overall density of the Universe and the details of particle physics, G. Steigman (Bartol Research Foundation) gave an impressive argument that this low value (which is significantly lower than the often-adopted $Y = 0.25$) places constraints on particle physics if a density for the Universe can be assumed. In particular, it may limit the allowed number of neutrino types (whose flavours had been threatening to outnumber those available at the local ice-cream parlour) to only two or three.

Many other problems were discussed at Santa Cruz, and if the function of a good workshop is to raise more questions than it answers, then this one certainly succeeded! □

Why are there fewer frogs and lizards in Southeast Asia than in Central America?

from Robert M. May

It has long been suspected that the densities of floor-dwelling amphibians and reptiles are lower in the rainforests of Southeast Asia than in those of Central America.

The first quantitative analysis, however, was made by Scott (*Biotropica* **8**, 41; 1976), who compared his data from two Costa Rican forests with that of Lloyd *et al.* (*Am. Nat.* **102**, 497; 1968) from Nanga Tekalit in Borneo. Inger (*Am. Nat.* **115**, 761; 1980) has recently widened the scope of such comparisons, combining his own additional data from Bornean, Malayan and Thailand forests with Heatwole and Sexton's (*Am. Midl. Nat.* **75**, 45; 1966) results for Panamanian rainforests. The main results are summarized in the Table.

By and large, the numbers in the Table are for floor-dwelling creatures, omitting arboreal and riparian-terrestrial animals (though the Panamanian study includes some lizards captured on trees). Inger notes that turtles and snakes were found too rarely for it to matter whether they are included; similarly, the Costa Rican numbers are little affected by adding in salamanders (as Scott did).

Inger presents further data on the daily catch of frogs and lizards in two other rainforest sites in Borneo, and in three sites (rainforest, logged forest, rubber planting) in Malaya. Although absolute estimates of individuals per m^2 are not available for these sites, the number of catches per day in the rainforest sites were so similar to those in the Old World sites listed in the Table that it is reasonable to assume the densities would also have been similar. On the other hand, the catch per day in the two disturbed sites (logged forest and rubber plantings in Malaya) were more than twice the rates in undisturbed Old World rainforests. Inger suggests this may be due to environmental factors, or to the abundance of species that might be called commensals of man; it could alternatively be due to the enhanced abundance often associated with the 'r-selected' species that characterize disturbed habitats.

The Table shows a consistent pattern, with the total density of frogs and lizards in rainforests in the New World being an order of magnitude higher than those in Southeast Asia. This overall pattern conceals some interesting details. One such is the reversal of the preponderance of frogs over lizards as one goes from Borneo to Thailand; Inger and Colwell (*Ecol. Monogr.* **47**, 229; 1977) attribute this to the relatively dry, harsh seasonal climate of the Thailand sites, which would favour reptiles over amphibians.

What is the explanation for the striking differences revealed in the Table? In terms of ecological roles, species of frogs and lizards dwelling on the floors of tropical forests are very similar; in both Old and New Worlds, the majority feed on arthropods and other invertebrates, and both groups inhabit the same kind of microhabitat. The total number of species of frogs and lizards (species richness) is not significantly different between the two hemispheres. The abundance of snakes or other important predators of frogs and lizards does not show systematic differences.

Comparison of densities of floor-dwelling amphibians and reptiles in lowland (<500m) forests of Old and New World tropics.

Place	Individuals per 100 m^2		
	Frogs	Lizards	Combined
Borneo: Nanga Tekalit	1.31	0.25	1.56
Thailand: Sakaerat			
evergreen forest	0.12	1.03	1.15
deciduous forest	0.27	1.22	1.49
Costa Rica: Rincon de Osa	11.6	3.9	15.5
Costa Rica: La Selva	14.7	2.8	17.5
Panama: Silugandi	29.8	15.4	45.2

Scott attributes the difference in density to there being less production of litter in Bornean forests. But Inger shows some of the estimates of litter production in Bornean forests used by Scott are inappropriate (coming from impoverished heath forests), while others have been revised upward by later work. It does not now seem that production of litter varies much among the major tropical rainforests.

Inger's explanation begins with the observation that a high proportion of the trees in Indo-Malayan rainforests are members of one family, the Dipterocarpaceae. Dipterocarps are noted for their synchronized mast fruiting, which often involves more than 100 species over thousands of square kilometers; the intervals between such reproductive explosions exceed one year. This phenomenon has, however, not been reported for trees in Neotropical forests. Inger suggests that "Mast fruiting should lead to reduction in abundance of an entire class of arthropod primary consumers during non-mast years. In turn, this reduction should affect the total size of the insect population and, therefore, the numbers of insectivorous secondary consumers, such as frogs and lizards. Since ripe dipterocarp seeds do not hang but fall to the ground, it is likely that a reduction in the numbers of seed-eating insects and their arthropod predators would have its greatest effect on the food supply of terrestrial rather than arboreal frogs and lizards."

Inger notes that his hypothesis is susceptible to several tests. If his ideas are correct, both the total number of insects, and the proportion comprising fruit and nut eating insects, should be lower on the floors of Southeast Asian forests than in the Neotropics. Similarly, we would expect to find fewer insectivorous birds feeding on or near the ground.

If Inger's suggestions survive these tests, the problem will have been pushed back one notch. We will then need to understand whether it is historical accident or systematic environmental differences that have produced spectacularly synchronized mast fruiting in Southeast Asian forests and not in the New World. ☐

Neurotoxicity: Mechanisms explored and exploited

from M.K. Johnson

New knowledge of the mechanism of delayed neurotoxicity of some organophosphorus esters is enabling realistic assessment of hazardous levels of exposure. Tri-aryl and mixed alkyl-aryl phosphate esters are widely used as hydraulic fluids, flame retardants and plasticisers and, in both agriculture and disease vector control programmes, organophosphorus pesticides are now used in preference to the persistent halogenated hydrocarbons. Some, but not all, of these esters cause delayed neuropathic effects when tested in sensitive species such as hens or cats and similar neuropathies have occurred in man after ingestion of organophosphates. There is an interval of 10-15 days between ingestion of a neuropathic ester and the onset of clinical signs and, until recently, clinical observation has been the most sensitive tool of the neurotoxicity tester.

At a recent conference* the primary causal molecular changes were presented and the ways in which this knowledge could

M.K. Johnson is in the MRC Toxicology Unit, Carshalton, Surrey, UK.

0028-0836/80/370105-02$01.00

be applied in design and safety evaluation were discussed. M.K. Johnson (MRC Toxicology Unit, UK) showed that many macromolecular sites in nervous tissue are phosphorylated within a few hours of dosing hens with a radio-labelled neuropathic organophosphate. These sites have been dissected into sets and sub-sets by selective use of inhibitors and the delayed neurotoxicity protein phosphorylation site identified unambiguously in one sub-set. The initiation mechanism comprises a phosphorylation of the target protein followed by a bond-fission to form a charged monosubstituted phosphoryl group bound to this site.

Reports at the Round-Table focussed on the fact that the phosphorylation site can hydrolyse phenyl valerate and that toxic attacks on the site can therefore be assessed using the 'neurotoxic esterase' (NTE) as a biochemical monitor. Even at doses producing no clinical or histological effects during the critical 10-15 day period after dosing a response of NTE inhibition at 1-2 days can be observed and quantified. This provides a means to grade the toxic response in a way superior to the previous yes-or-no evaluations.

M. Lotti (Padua University) has studied autopsy samples of human nervous tissue. He finds that *in vitro* the inhibition characteristics of acetylcholinesterase (AChE) and NTE from man are similar to those from the hen. In both species organophosphate poisoning causes cholinergic death only if AChE is highly inhibited. Further, in hens neuropathy is caused only if the maximum inhibition of NTE is greater than 70–80%. To evaluate the hen further as a model we need to know whether equally high inhibition of human NTE is a prerequisite of neuropathy in man. Autopsy material is required from cases of poisoning by compounds which are known to be able to cause neuropathy in sub-lethal doses. The degree of NTE inhibition in the lethal cases should give some guide to the threshold associated with neuropathy. Appeal was made for both NTE and AChE assays to be made whenever deaths occur from organophosphate poisoning; the causative agent should also be proven by tissue analysis and not presumed.

Lotti has carried out such an assay for a case of poisoning by the insecticide omethoate. Although AChE was highly inhibited there was no inhibition of NTE suggesting that neuropathic consequences are not to be expected from survivors of poisonings by omethoate in man. Lotti also showed that doses in excess of the LD_{50} of omethoate did not inhibit brain NTE or cause neuropathy in hens either, again suggesting the hen may be a useful model.

Neural biopsies are obviously unsuitable for monitoring but R. J. Richardson (Ann Arbor) showed that the accessible blood lymphocytes contain an esterase identical to NTE in a variety of its biochemical properties. Provided that the natural fluctuation of lymphocyte levels can be allowed for, routine assay of lymphocyte NTE in potentially exposed persons such as spraymen may allow a neuropathy monitoring system analogous to the assay of blood AChE for acute poisoning.

At the LD_{50} dose diethyl phosphates are always more likely to cause neuropathy than the analogous dimethyl esters. This can be rationalised by analysing effects on NTE independently of all other factors such as metabolic disposal. Study of structure/activity relationships for inhibition of NTE *in vitro* provides a basis for design of non-neuropathic anticholinesterase pesticides. For instance it has been found that esters with hydrophilic or heterocyclic leaving groups have comparatively little affinity for NTE in the test tube and low neuropathic potential *in vivo* and that insecticidal carbamates have no neuropathic potential.

In vivo phosphorylation of the neurotoxicity protein site by neuropathic esters occurs within a period ranging from a few minutes to two days after dosing depending on the route of administration and on whether they require metabolic activation. The secondary bond-cleavage is very rapid in most cases studied but there is then a silent period of about one week before axonal degeneration begins. A. Bischoff (University of Berne) reported that the earliest morphological changes are swellings of some rounded synaptic vesicles at excitatory nerve terminals. These changes were seen at a time when no such changes occurred in the flattened (inhibitory) vesicles although clinical signs of neuropathy were already apparent.

Toxicity testers are already reaping benefit from the understanding of the earliest events. As understanding is extended to the events in the silent period it is hoped that the processes by which axons are maintained may become clearer. Such understanding may be relevant to the modes of action of a wider range of neuropathic chemicals than only the organophosphorus esters. □

*A symposium on "Recent Developments in Mechanisms of Neurotoxicity" and a Round-Table discussion on "Delayed Neurotoxicity Testing of Organophosphates" were linked during the Second International Congress of Toxicology in Brussels, 6th — 11th July 1980.

Laser polarization labelling

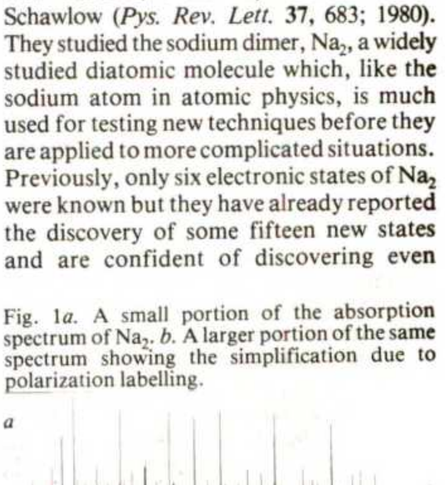
from Allister I. Ferguson

'A diatomic molecule is a molecule with one atom too many'. This definition, which was coined by Arthur L. Schawlow reflects the kind of despair most spectroscopists encounter when attempting to unravel the complexities of molecular spectra. Even the simplest molecules have such a complicated structure that identifying and assigning quantum numbers to spectral lines is a major task. However, using a laser polarization labelling technique Schawlow and his colleagues at Stanford University have been able to simplify molecular spectra so that the spectra they obtain are more typical of atoms than of molecules. They have been able to identify new highly excited electronic states in a simple diatomic molecule and there are now good prospects for the application of the method to much more complicated molecules.

The factor which complicates molecular spectroscopy is that in addition to the electronic energy levels, which gives rise to atomic spectra, a molecule can vibrate and rotate. These vibrations and rotations add to the electronic energy levels changing a series of isolated levels into a complicated picture of overlapping bands. However, the Stanford group's technique enables a particular level within a band to be 'labelled' so that transitions from this 'labelled' level can be observed and a tremendous simplification in the spectrum be obtained.

The latest research has been reported by Nils Carlson, Toni Taylor and Arthur Schawlow (*Pys. Rev. Lett.* **37**, 683; 1980). They studied the sodium dimer, Na_2, a widely studied diatomic molecule which, like the sodium atom in atomic physics, is much used for testing new techniques before they are applied to more complicated situations. Previously, only six electronic states of Na_2 were known but they have already reported the discovery of some fifteen new states and are confident of discovering even

Fig. 1*a*. A small portion of the absorption spectrum of Na_2. *b*. A larger portion of the same spectrum showing the simplification due to polarization labelling.



Allister I. Ferguson is in the Department of Physics, Clarendon Laboratory, University of Oxford.

0028-0836/80/370106-02$01.00

more in the near future. With a method powerful enough to find so many new states in such a well understood and highly studied molecule it is tantalising to speculate on the kind of discoveries which might be made on more exotic and less well understood molecules.

The technique that they use was first developed by Richard Teets, Richard Feinberg, Theodor Hänsch and Arthur Schawlow (*Phys. Rev. Lett.* **17,** 683; 1976) and they called it laser polarization labelling. The method uses as a light source a narrowband tunable laser which can excite molecules from isolated vibrational-rotational levels of the ground electronic state to an electronically excited state. If the intensity of the laser is sufficiently large a significant proportion of the population of molecules in the lower level will be transferred to the upper level. By choosing the polarization of the laser appropriately it is possible to orient the levels of the transition in such a way as to create an optical anisotropy in the medium. These levels are said to be 'labelled'. This anisotropy will be experienced by light which is resonant with one of the 'labelled' levels and some other level. Now if broadband light is passed through the medium most of the light will be transmitted without change in polarization. However those light frequencies which do resonate with one of the 'labelled' levels and another level will suffer a depolarization. This depolarization can easily be detected by passing the light through a crossed polarizer. Only those frequencies which interacted with the 'labelled' levels will be transmitted and the spectrum of the this light can be recorded with a spectrograph.

The number of levels that can be reached from a particular 'labelled' level is quite limited due to the quantum mechanical selection rules. In fact, for each 'labelled' level there are at most three rotational levels which can be accessed for each vibrational state. Further selection rules often reduces this number to two.

A typical polarization labelled spectrum in shown in Fig. 1. This shows a small part of the spectrum of Na_2. The pairs of lines in Fig. 1 *b* correspond to the two allowed transitions from each 'labelled' level for each vibrational state. These are the P and R branch transition in the terminology of molecular spectroscopy. Each pair of lines correspond to transitions to different vibrational levels of the excited electronic state. By scanning a wide enough spectral region it is possible to identify the lowest vibrational level and the vibrational and rotational quantum numbers can be found. Given these the molecular constants for the electronic state can then be easily calculated. The classification of the electronic state is determined by selection rules. Also shown in figure 1 *a* for comparison is a traditional absorption spectrum of a much smaller portion of the Na_2 spectrum. Clearly identification of particular electronic states and vibrational and rotational quantum numbers from such a spectrum is extraordinarily difficult.

Carlson *et al.* have scanned wide regions of the Na_2 spectrum and have managed to identify no fewer than fifteen new electronic states. Ten of these states are characterised as being $^1\Delta_g$ and five as $^1\pi_g$. The energies of these new states have been found to follow the well known Rydberg formula, with small corrections due to molecular symmetry. The states are found to correspond to principal quantum numbers of n = 6–15 for the $^1\Delta_g$ states and n = 4–8 for the $^1\pi_g$ states. It should be possible to also find new Σ states and the Stanford group have begun the search for these.

The study of highly excited molecules (Rydberg molecules) has been severely hampered by the very complex structure of the closely spaced Rydberg molecular levels. At the same time studies of Rydberg atoms have been very fruitful (Metcalf *Nature* **284,** 127; 1980) — so much so that Rydberg spectroscopy is now a sub-branch of atomic physics. The work of Carlson *et al.* is a breakthrough in unravelling and interpreting the Rydberg molecule and is the first step to a new and fuller understanding of highly excited molecules which should open the way to Rydberg molecular spectroscopy. □

Combination chemoprevention of cancer

from Michael B. Sporn

THE current use of cytotoxic drugs for treatment of invasive cancer in man depends largely on combination chemotherapy — the combined use of several drugs which exert synergistic effects to achieve the goal of total tumour cell kill. Several papers presented at a recent meeting* suggest that for similar reasons 'combination chemoprevention' might be of importance in the future development of non-cytotoxic drugs for prevention of cancer, that is, for the arrest or reversal of the development of neoplasia in its premalignant stages. Recent advances in the under-standing and control of tumour progression (promotion) have been particularly striking. Using the classical two stage model of mouse skin carcinogenesis (the hydrocarbon, DMBA, as initiator, and the phorbol ester, TPA, as promoter), A.K. Verma and R.K. Boutwell (University of Wisconsin) reported that the combinations of either retinoic acid plus the steroid, dexamethasone, or retinoic acid plus the protease inhibitor, TLCK, exert marked synergistic preventive effects. Their results suggest that retinoic acid, dexamethasone, and TLCK inhibit skin tumour promotion by independent mechanisms. Similar conclusions were reached recently by T.J. Slaga *et al.* (Oak Ridge National Laboratory; *Proc. natn. Acad. Sci. U.S.A.* **77,** 2251; 1980) who have shown that the promotion stage in this system can be further divided into two stages, with the first stage caused by limited application of TPA, and the second caused by the related weak diterpene promoter, mezerein. Slaga *et al.* suggest that low doses of TPA induce formation of primitive skin stem cells, while mezerein induces formation of polyamines and resultant cell proliferation. The TPA effect can be blocked by the protease inhibitor, TPCK, while the mezerein effect is blocked by retinoic acid; glucocorticoids apparently inhibit both stages of promotion. In other studies, Verma, Ashendel, and Boutwell (*Cancer Res.* **40,** 308; 1980) have shown that retinoic acid and indomethacin, an inhibitor of prostaglandin synthesis, exert a synergistic effect to block the induction of ornithine decarboxylase (ODC) caused by TPA; ODC activity has been previously implicated as a key step in formation of polyamines. Whether retinoids and inhibitors of prostaglandin synthesis are synergistic for prevention of skin tumours in the mouse is currently being studied.

Another important area for studies of initiation and promotion is mammary carcinogenesis, in which the internal hormonal milieu of the organism is believed to provide the required promotional stimulus for development of cancer. In the female rat, one or two doses of the alkylating carcinogen, nitrosomethylurea, suffice to initiate carcinogenesis. In new studies, C.W. Welsh (Michigan State University) and R.C. Moon (IIT Research Institute) reported that the combined use of a suppressor of prolactin secretion (2-bromo-α-ergocryptine) together with the retinoid, retinyl acetate, was distinctly superior to either treatment alone in preventing mammary cancer after rats were treated with the carcinogen. Prolactin has long been suspected as a promoting agent in human mammary carcinogenesis, and suppression of its secretion has an obvious rationale. The molecular mechanism of action of the

---

*Annual Meeting of the American Association for Cancer Research, San Diego, California, May 28-31, 1980.

0028-0836/80/370107-02$01.00

retinoids in this system is not known, although it has been shown (Moon *et al.* *Cancer Res.* **39,** 1339; 1979) that they have an anti-proliferative effect on mammary epithelium.

Combination chemoprevention also is applicable to inhibition of the initiation of cancer, as was reported by P.W. Dion, W.R. Bruce *et al.* (Ontario Cancer Institute). It had previously been shown by Bruce's group that mutagenic substances (assayed by the Ames test) are found in human faecal material, and they have been suggested as possible endogenous causative agents for colon cancer. Since it is suspected that these mutagenic substances may be N-nitroso derivatives of intestinal lipids, Bruce *et al.* have fed ascorbic acid and α-tocopherol (known inhibitors of nitrosamine formation) to human volunteers. They reported that the combination of ascorbic acid and tocopherol reduced the median level of faecal mutagen to 25% of control values; the rationale for the combination is to achieve an effective level of anti-oxidant in both the aqueous and hydrophobic phases of the intestinal contents. Another important observation relating to ascorbic acid and cancer prevention was reported by W.F. Benedict and P.A. Jones (University of Southern California), who have shown that levels of ascorbic acid as low as 1 μg per ml can inhibit malignant transformation of mouse fibroblasts caused by methylcholanthrene in cell culture. They found that ascorbic acid was effective in blocking transformation when given as late as 3 weeks after exposure of cells to the carcinogen. Previously, ascorbic acid had been considered to be of chemopreventive use only as an anti-initiating agent. Benedict and Jones' new studies (see also *Cancer Res.* **40,** 2796; 1980) suggest that ascorbic acid may also function as an anti-promoting agent, and will undoubtedly add further interest to the already controversial area of the use of this compound in treatment and prevention of malignancy.

Whatever may be the outcome of these studies, the field of combination chemoprevention appears to be developing rapidly. In other areas of pharmacology the use of multiple drugs to achieve synergistic action and to diminish toxicity is well established. At present, it cannot be predicted how successful such methods might be for applied chemoprevention in man. However, as interest in pharmacological prevention of cancer increases (and as concern about the possible toxic effects of some of the preventive agents, particularly the retinoids, also increases), combination chemoprevention will undoubtedly attract further attention. □

Adenovirus complexities

from correspondents

Two years ago splicing was the hottest subject of discussion at the EMBO workshop on the molecular biology of adenoviruses but the latest meeting* showed that many of the details of complex splicing patterns have already been untangled. Now, the control of virus transcription and DNA replication remain to be elucidated and there has been a clear trend to the development of *in vitro* systems to dissect further the intricacies of eukaryotic cellular control mechanisms.

In vitro transcription systems derived from uninfected KB or HeLa cells with purified RNA polymerase have been used to define the requirements for specific *in vitro* initiations of viral transcription (Lee, University of St. Louis and Corden, University of Strasbourg). Lee used cloned viral DNA fragments as templates to show that the major late promoter is used to initiate RNA products in the correct direction and of the size predicted from the size of the DNA fragment used. All other *in vivo* promoters are also active *in vitro* with the notable exception of the E2 promoter at 75 map units; it is known from sequence analysis that this site lacks a recognisable 'TATAA' box. The promoters vary in strength in the *in vitro* system over a tenfold range, with the major late promoter being most active and early E1A the least active. By using as template a DNA fragment that included the whole of the polypeptide IX transcription unit (the sequence of which is known and which is not spliced *in vivo*), Lee also showed that in his system at least, termination does not occur at a specific site. Transcription continues through the known poly A addition site and very large RNA products are obtained.

Corden, using a similar *in vitro* system, has introduced specific deletions into the DNA template in the region of the major late promoter, to define the sequence requirements for specific initiation of transcription. Removal of bases more than 31 positions upstream from the cap site, or after the site of initiation, did not inhibit *in vitro* transcription, but removal of bases at -31 or -30 resulted in a five-hundred fold reduction in initiation. Similar experiments defined the 5'' promoter boundary at -12 relative to the cap site. In analagous experiments using cloned conalbumin promotor DNA, Corden showed that changing T to a G in the TATAA box lying within the promoter region also reduces the rate of initiation substantially.

Mathews (Cold Spring Harbor) concluded from the hybridization experiments that the non-coding Ad-2 VA RNAs may play a role in virus messenger RNA splicing. Flint (Princeton University) using antibodies from patients with systemic lupus erythmatosus which immunoprecipitate different classes of human ribonucleoproteins reported that some of these antisera inhibit the splicing of Ad-2 early RNA in nuclei isolated from cells infected for 8 hours in the presence of cytosine arabinoside.

Another *in vitro* system that continues to yield intriguing information is that for DNA synthesis. Kelly (Johns Hopkins University), Stillman (Cold Spring Harbor) and Winnacker (München University) showed that nascent DNA chains initiated *in vitro* have terminal protein covalently attached to the 5′ end. Kelly further showed that the polypeptide attached *in vitro* has a molecular weight of 80K in contrast to the 55K product seen on mature virion DNA. However, pulse chase experiments *in vivo* suggest that the 80K form may be a precursor of the 55K protein. Furthermore, they give the same patterns of partial proteolysis with chymotrypsin and are attached to the DNA by the same linkage; a phosphodiester bond between the ß-OH group of serine and the 5′-OH of the terminal deoxycytidine in the DNA.

By stringently inhibiting host cell protein synthesis with anisomycin Lewis (Cold Spring Harbor) reported that his group have identified a new class of 'immediate early' Ad-2 proteins. One of these proteins, which is encoded between 17.0 and 21.5 map units, was clearly shown to be synthesised independent of 'early' region 1A.

Evidence was presented by a number of groups that the Ad-2 major late promoter (co-ordinate 16.4) functions 'early' after infection in permissive cells. Ziff (Rockefeller University) demonstrated by RNase T-1 finger printing that the capped undecanucleotide and promotor proximal spots 1-4 could be clearly identified in cycloheximide treated cells 2-4 hours post infection. Lewis and Akusjarvi (Uppsala University) both identified *in vitro* synthesised proteins (52K and 55K) using Ad-2 m-RNA transcribed from the major late promoter in drug blocked infected cells. Akusjarvi also reported that both of these proteins are synthesised *in vivo* in infected cells blocked for DNA synthesis using cytosine arabinoside.

This meeting produced no definitive data to clarify which adenovirus gene(s) or products are responsible for transformation or malignancy. Past failure to isolate adenovirus conditional lethal mutants defective for transformation has encouraged several groups (Williams, University of Pittsburgh; Ginsberg,

---

*The meeting was held at Peebles, Scotland, June 14-18, 1980.

Columbia University and Jones, Purdue University) to use molecular biology techniques and/or *in vitro* mutagenesis to create new mutants. Williams described a 'cold sensitive' mutant which apparently lacks transforming ability. He also reported that the ability of a virus to stimulate host cell DNA synthesis was not alone sufficient to induce transformation. Jones reported studies on an Ad-5 mutant that lacked a single transcript from early 1A which they had generated by inserting an octanucleotide (GGAATTCC) into the Sma I site at 2.85 map units. Preliminary data suggest that this insertion affects transformation.

A number of papers were presented which clearly show that adenovirus DNA is integrated into rodent DNA by illegitimate recombination events. Sambrook (Cold Spring Harbor) Ad-2, Visser (Utrecht University) Ad-5 and Stabel (Cologne University) Ad-12, provided data that for each transformed cell line studied viral integration had occurred at different sites in the host genome. Van den Elsen (University of Leiden) reported that the oncogenicity of Ad-5 and Ad-12 transformed baby rat kidney cell lines in nude mice required the expression of the entire 'early' regions 1A and 1B. Cell lines not expressing 1B 65K protein (Ad-5) or 1B 60K protein (Ad-12) were found to be non-tumourigenic. Graham (McMaster University), reporting on similar experiments using baby hamster kidney cells, concluded that in this system tumourigenic cell lines could be obtained by transfection of Ad-5 DNA which represented early region 1A, but only part of early region 1B (HIND III G fragment).

Raska (CMDNJ — Rutgers) using both serum and cell mediated cytotoxic techniques *in vitro* demonstrated that Ad-12 'early' region 1 codes for a membrane associated antigen. This may be the bonafide virus specific transplantation antigen. However, it is also known that some transformed rat cell lines have a membrane glycoprotein bound to the major histo-compatability antigens. The precursor virus protein of the membrane bound glycoprotein is 16K and is encoded in early region 3.

In conclusion, it seems likely that the next two years of adenovirus research will be dominated by molecular engineering and *in vitro* systems with *in vitro* mutagenesis providing the geneticists with a powerful tool to define more clearly which gene(s) is responsible for malignant transformation and which proteins are involved in transcriptional control of this complicated unit of genes. □

Polymerase III control region defined

from Peter J. Ford

RECENT experiments show that in at least one class of eukaryote genes — 5S ribosomal RNA genes transcribed by RNA polymerase III — control of RNA synthesis is quite different from that found in prokaryotes. In a typical prokaryote gene a promoter site, which binds RNA polymerase, is situated about 10 base pairs upstream (to the 5′ side) from the site at which transcription begins. Mutations in the promoter site alter the level of gene expression but do not affect the actual control of expression. A second site, the operator, overlapping the polymerase binding site is found about 20 base pairs downstream (to the 3′ side) of the initiation site. The operator binds a repressor molecule which prevents polymerase from binding to promotor. Control is exercised by the interactions of small molecules which facilitate either the removal or the binding of the repressor to the operator site. Thus the prokaryote gene consists of a regulatory site overlapping a polymerase binding site located at or just upstream from the point at which transcription begins.

In prokaryotes all genes are transcribed by a single RNA polymerase. In eukaryotes, however, there are at least three structurally and functionally distinct RNA polymerases. Polymerase I transcribes only ribosomal RNA, polymerase II transcribes heterogeneous nuclear RNA (mRNA precursors) and polymerase III trancribes a variety of low molecular weight RNAs including transfer RNAs, 5S ribosomal RNA, low molecular weight RNAs and viral-associated low molecular weight RNAs. The small size of the Polymerase III primary transcripts makes their identification easy and this coupled with their lack of post-transcriptional processing has made genes transcribed by Polymerase III the first choice for studies of regulation.

The somatic 5SRNA gene of *Xenopus borealis* was chosen by Sakonju, Bogenhagen and Brown (*Cell* **19**, 13; 1980) in their search for the eukaryote promoter site. A single 5S gene copy cloned in pBR322 can promote faithful transcription (correct initiation and termination) of 5S RNA in an *in vitro* and an *in vivo* (oocyte injection) assay. By an *in vitro* genetic engineering procedure regions flanking both 5′ and 3′ ends of the gene were deleted and the deleted genes recovered after reinsertion into pBR322. Deletion end points were determined by sequencing the DNA and were numbered from the transcription initiation site (position + 1), base pairs downstream (within the gene) being numbered +2, +3, . . . and base pairs upstream being numbered -1, -2 -3 and so on.

Genes with deletions extending into them from the 5′ end were tested for transcription activity in an *in vitro* transcription assay (Birkenmeier, Brown & Jordan *Cell* **15**, 1977; 1978). It was shown that genes with all 5′ flanking sequences deleted up to the intiation site are actively transcribed but begin at an incorrect site a few nucleotides into the gene, suggesting that the 5′ flanking sequence is required for correct initiation but does not control transcription. Deletions were made extending further into the gene but not until 50 base pairs had been removed was there a drop in transcription efficiency. Remarkably, the size of the transcripts remained about 120 nucleotides, the size of normal 5SRNA. Thus polymerase III is recognizing a sequence starting at least 50 base pairs into the gene from the normal initiation site and is beginning transcription on any appropriate base pair in the region where the normal initiation site should have been put even though this is now replaced by vector pBR322 DNA.

Two points are evident — polymerase binding and transcription depend on a site within the gene itself while the exact point of initiation is influenced by the sequence surrounding the initiation site. To test the relative importance of these two effects Sakonju *et al.*, constructed two 'maxigenes' which had an extra 6 or 20 base pairs inserted between positions +40 and +41 of the gene sequence. Maxigenes are transcribed to give 5S sized transcripts which have begun transcription at sites within the gene. For the +6 maxigene the initiation point is at +10 or +11 base pairs and for the +20 maxigene the initiation point is at either position +21, +22, +23 or +24 within the normal gene sequence. Thus the site within the gene is dominant over the sequence at the normal initiation site, and acts to promote initiation at any convenient site at a loosely fixed distance (about 50 base pairs) upstream from that site, the precise initiation point being determined by the local sequence(s) surrounding potential initiation sites.

Transcription experiments were also carried out with genes deleted progressively from the 3′ end (Bogenhagen, Sakonju & Brown *Cell* **19**, 27; 1980). Since deletions of the 3′ end lack a correct termination site a technique for identifying correct initiation in the absence of correct termination had to be used. Cordycepin triphosphate (3′ dATP) was included in the *in vitro* assay mix serving to terminate a proportion of transcripts at each A residue in the gene sequence. Correct initiation generates a defined set of molecules (analogous to a sequencing ladder) which can be

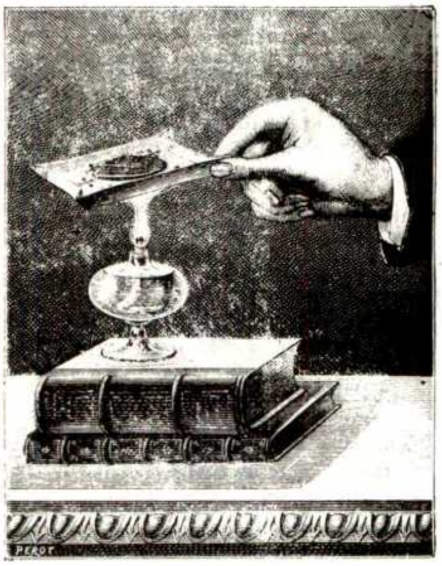
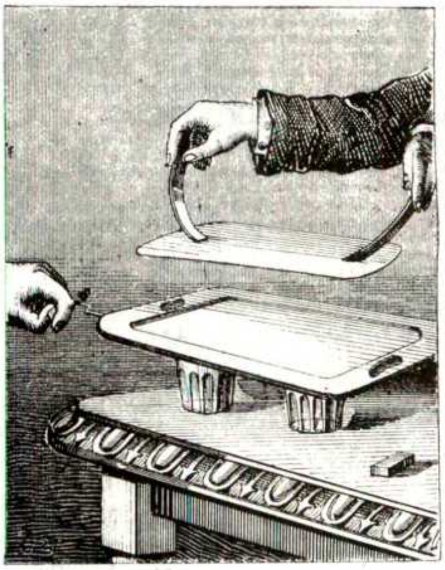
PHYSICS WITHOUT APPARATUS



Melting lead on a playing card

A pretty experiment which is easily performed is that of boiling water in a sheet of paper. Take a piece of paper and fold it up, as schoolboys do, into a square box without a lid. Hang this up to a walking-stick by four threads, and support the stick upon books or other convenient props. Then a lamp or taper must be placed under this dainty cauldron. In a few minutes the water will boil. The only fear is lest the threads should catch fire and let the water spill into the lamp and over the table. The flame must therefore not be too large. A small taper will give a flame quite large enough. The paper does not burn, because it is wet; and even if it resisted the wet it still would not burn through, because the heat imparted to it on one side by the flame would be very rapidly conducted away by the water on the other. Another experiment of a similar nature, but perhaps even more striking, is as follows: — Twist up the edges of a common playing-card or other bit of eardboard, so as to fashion it into a light tray. On this tray place a layer of small shot or bits of lead, and heat it over the flame of a lamp. The lead will melt, but the card will not burn. It may be charred a little round the edges, but immediately below the lead it will not be burned, for here again the lead conducts off the heat on one side as fast as it is supplied on the other. Lastly, we give an experiment which, like the two preceding, proves that a good conducting substance may protect a delicate fabric from burning by conducting away the heat rapidly from it. Lay a piece of muslin quite flat upon a piece of metal. A live coal placed on the muslin will not burn it, for the metal takes away the heat too fast. If the muslin is however laid on a bad conductor, such as a piece of wood, it will not be protected, and the live coal will kindle the muslin.

A certain way to obtain an electric spark we have found with what we may call a *Tea-tray Electrophorus.* A common tea-tray of metal is supported on two dry glass tumblers. A piece of common brown paper cut so as to be a little smaller than the tray, and with rounded corners, is warmed, laid on the table and rubbed briskly with a piece of indiarubber, or with a clothes-brush. It is then laid down for an instant on the tray and the tray is touched with the hand. The brown paper is then lifted a few inches above the tray. If at this juncture some person presents his knuckle to the tray he will receive a birght spark, which under favourable circumstances may be a couple of inches long. By simply putting the paper down, touching the tray, and again lifting up the paper the tray is again charged: and a large number of sparks may be thus drawn one after the other in rapid succession. The paper may be lifted by the hands, but it will be found better if a couple of ribbons or strips of paper be fixed on with wax to serve as handles, as shown in our figure.



The Tea-tray Electrophorus.

From *Nature* **22,** 9 & 16 September, 440 & 464, 1880.

recognized by their electrophoretic mobility in acrylamide gels. By such means the 3′ end of the gene could be deleted to between +80 and +83 of the gene sequence before correct initiation failed. Together with the previous result this defines the region in *X. borealis* somatic 5S DNA which is required for transcription as lying between positions +50 and +83 of the gene sequence.

An internal promoter is certainly unexpected and different in location from the 5′ flanking promoters of bacterial genes, but is it a general rule for all polymerase genes? The answer is probably yes since there is significant homology of a sequence AGCAGGGT found between base pairs +55 and +62 of the 5S gene and a similarly (±2 base pairs) located sequence in other polymerase III genes — Adenovirus VA I gene and *Bombyx mori* tRNA^{tyr}.

Moreover, similar deletion and transcription studies on tRNA genes (Telford *et al. Proc. natn. Acad. Sci. U.S.A.* **76,** 2590; 1979) show that deletion of 5′ flanking sequences to within −20 base pairs of the transcription initiation site does not impair transcription of the *Xenopus laevis* $\text{tRNA}_1^{\text{met}}$ gene. However, a mutation (Ad5d1309, a dimer deletion) occuring outside the gene between pairs −21 and −24 of the 5′ flanking sequence of adenovirus 5 VA I gene does prevent synthesis of one of the two alternate VA I RNAs (Thimmappaya, Jones & Shenk, *Cell* **18,** 947; 1979). The two VA I RNAs are both transcribed from the same gene but differ by three nucleotides at the 5′ end, VA IA begins with pAGCG . . . while VA IG begins at the second G. The Ad5d1309 mutant produces only the VA IG RNA. The two base pair deletion thus alters the 5′ flanking sequence sufficiently to suppress initiation at A but not at G, demonstrating, in an *in vivo* situation, that local sequences influence the exact site at which transcription begins.

Clearly if the same polymerase III enzyme transcribes a wide variety of genes some of which are independently regulated there must be other factors interacting with the gene–polymerase complex to regulate transcription. One such factor has recently been purified from soluble extracts of *Xenopus* ovaries (Engelke, Ng, Shastry, & Roeder *Cell* **19,** 717; 1980). It had been noticed that 5S genes in chromatin from oocytes were transcribed by a purified polymerase III preparation but a cloned 5S gene was not (Ng, Parker & Roeder *Proc. natn. Acad. Sci. U.S.A.* **76,** 13; 1979). Activity could be restored to the purified polymerase III/cloned 5S gene system by addition of an ammonium sulphate fraction of soluble ovary proteins. Such restoration assays made it possible to purify a 37,000 molecular weight protein which allows faithfull transcription of both *Xenopus* somatic and oocyte cloned 5S genes in a defined reconstituted transcription system using purified polymerase III. The factor, which appears specific for 5S genes, has no activity on a cloned *Xenopus* $\text{tRNA}_1^{\text{met}}$ gene. The factor binds independently of polymerase III to a region of the 5S gene between +45 and +96 base pairs completely overlapping the region identified by deletion mapping as essential for transcription in 5S DNA. Thus there is a possibility that this factor acts in a positive way by directing polymerase III to the 5S gene. It seems certain that this is the first of many factors which will be found to specifically modify the interaction between polymerase III and its genes.

Thus the dogma generated by studies of gene regulation in prokaryotes is breaking down with the demonstration of an internal promoter and regulatory sites for 5S RNA transcription in *Xenopus*. These studies have not yet defined the nature of developmental regulation of these genes, but they have gone a long way towards that goal. □

The
Fraction Collector
for the '80s is here.

It's FOXY.™

FOXY, the Fraction-Optimizing X-Y fraction collector from ISCO. Microprocessor control permits collection by uniform or mixed time intervals, counted drops, pump revolutions, or ISCO Volumeter discharges. FOXY rejects void volumes and isolates peaks identified by elution times or detected by an ISCO UV monitor. And, it stops flow between tubes and at the end of the run.

FOXY takes practically any size test tube, 28 mm scintillation vials, and even 500 ml bottles. It holds up to 288 tubes in minimal bench space—the keyboard is only 21 cm wide.

To learn more about ISCO's smart generation fraction collector, write ISCO, P.O. Box 5347, Lincoln, Nebraska 68505 U.S.A.

Message sequences and short repetitive sequences are interspersed in sea urchin egg poly(A)$^+$ RNAs

Franklin D. Costantini*, Roy J. Britten & Eric H. Davidson

Division of Biology, California Institute of Technology, Pasadena, California 91125

At least half of the mass and most of the different single-copy maternal mRNA sequences in the egg are covalently associated with transcripts of short repetitive sequences. Only a restricted group of the diverse genomic repeat families are significantly represented. The messages fall into several hundred sets, each containing transcripts from a different repeat family.

THE sea urchin genome includes over 10^5 short repetitive sequence elements interspersed among the single-copy DNA regions[1]. Renaturation kinetics[1,2], as well as primary sequence data[3], indicate that the genomic repeats belong to several thousand distinct sequence families, which in general share little or no homology. Although the biological role of these sequences is unknown, recent studies have shown that almost all of the diverse repeat families are represented in a tissue-specific manner in sea urchin nuclear RNAs[4] and in unfertilized egg RNA[5]. The present work was undertaken to determine the nature of those repeat transcripts stored in the egg. We found that many of these transcripts are covalently associated with RNAs which have the characteristics of egg maternal messengers. Thus, repetitive sequences are interspersed in egg poly(A)$^+$ RNA [p(A)$^+$ RNA] and are included in a large majority of the diverse species of egg message.

Repeated sequence transcripts are included on many egg poly(A) mRNA molecules

According to earlier studies[5] most of the transcripts of short interspersed repetitive DNA sequences in the sea urchin egg are present on RNA molecules several thousand nucleotides long. The possibility thus arose that the repeat sequence transcripts are located on maternal message molecules. The egg of *Strongylocentrotus purpuratus* contains about 50 pg of maternal mRNA (about 1.5% of the total egg RNA) bearing poly(A) tails sufficiently long to promote binding to oligo(dT)-cellulose columns[6–8]. We refer to the egg RNA collected on such columns as the 'p(A)$^+$ RNA', although the flowthrough or 'p(A)$^-$ RNA' fraction apparently includes an approximately equal mass of maternal message, much of which is terminated by short 3' oligo(A) tails which bind to poly(U)-Sepharose and not to oligo(dT)-cellulose[6–9]. Isolation of the p(A)$^+$ fraction of the egg RNA provides a convenient experimental enrichment for at least a large subclass of the maternal message. In addition, use of this fraction minimizes the contribution of known repetitive gene transcripts such as the histone mRNAs, which, in the sea urchin, do not co-purify with p(A)$^+$ RNA[10].

The p(A)$^+$ RNA of the egg was isolated and purified by successive rounds of oligo(dT)-cellulose chromatography. The denatured weight-average length of the p(A)$^+$ RNA was about 5,000 nucleotides, in general agreement with previous measurements[7,11]. This was determined by electron microscopy and gel electrophoresis as described below. The concentration of repetitive sequence transcripts was examined in the p(A)$^+$ RNA and the p(A)$^-$ RNA fractions. Figure 1*a* and *b* displays titration reactions with two cloned repetitive sequences, CS2109B and CS2108, shown earlier to be represented by prevalent egg transcripts[5]. The cloned probes were labelled and strand-separated, and one strand of each was reacted with increasing amounts of egg p(A)$^+$ RNA or p(A)$^-$ RNA[4]. Transcripts complementary to the CS2109B sequence (Fig. 1*a*) are 32-fold more concentrated in p(A)$^+$ RNA than in p(A)$^-$ RNA, and a similar degree of concentration, 38-fold, is observed for the CS2108 sequence (Fig. 1*b*). Given that 1.5% of egg RNA is included in the p(A)$^+$ RNA fraction, these results require that at least a third of the RNA molecules reacting with the two cloned repeats contain long poly(A) tracts.

To determine whether these two cloned repeats are representative, we measured the kinetics of the reaction of a ^{3}H-DNA genomic repetitive sequence tracer with excess egg p(A)$^+$ RNA, p(A)$^-$ RNA and total egg RNA. As shown in Fig. 1*c*, all three reactions were heterogeneous in rate, due to variation in the prevalence of different repeat trancripts[5]. However, it is clear that transcripts of most repeat families detectable in egg RNA are concentrated in the p(A)$^+$ RNA fraction. Considering the initial 30% of each reaction, which represents the more prevalent repeat transcripts, the reaction with p(A)$^+$ RNA occurs about 33 times more rapidly than with unfractionated egg RNA. Hybridization with p(A)$^-$ RNA is not detectably slower than with total egg RNA, so not all repeat-containing molecules are included in the p(A)$^+$ RNA fraction. It can be calculated from these data that about 50% of the transcripts of each average prevalent repeat species co-purifies with the p(A)$^+$ RNA fraction. For comparison, the distribution of single-copy sequence transcripts in the p(A)$^+$ RNA and p(A)$^-$ RNA of the egg is shown in Fig. 1*d*. The tracer in this experiment is a fraction of single copy ^{3}H-DNA selected by prior reaction with egg RNA ('egg DNA', or 'eDNA')[12]. Analysis of the kinetics shows that roughly half of the diverse species of single-copy sequence transcript present in the egg are heavily represented in the p(A)$^+$ RNA fraction. That is, an average of about 75% of the molecules of each RNA species in this class is recovered as p(A)$^+$ RNA. The other half of the mRNA species is mainly found in the p(A)$^-$ RNA fraction, though a small percentage of these molecules is included in the p(A)$^+$ RNA fraction, so that the two reactions ultimately terminate together. Of course, many RNA species may have

---

* Present address: Department of Zoology, University of Oxford, Oxford, OX1 3PS, UK.

0028-0836/80/370111—07$01 00

intermediate degrees of polyadenylation. Additional evidence has been obtained with cloned single-copy DNA probes. As reported elsewhere[13], about 50% of the prevalent transcripts of cDNA clone SpG30 are found in the egg $p(A)^+$ RNA fraction. Similarly, about 35% of the rare transcripts of the cloned Sp88 single copy sequence are recovered as $p(A)^+$ egg RNAs[14].

The distribution of repeat-sequence transcripts in $p(A)^+$ and $p(A)^-$ RNA fractions is consistent with the view that the repeats are found on $p(A)^+$ mRNA molecules. Thus, at least for those repeat families which are represented by prevalent egg RNA transcripts, about half of the molecules bearing each repeat sequence are recovered in the $p(A)^+$ RNA fraction. Furthermore, note that all the diverse repeat transcripts appear to be relatively concentrated in the $p(A)^+$ RNA fraction, while only about half of the different species of single-copy sequence transcript are recovered to a large extent as $p(A)^+$ RNAs.

Electron microscopy of renatured egg $p(A)^+$ RNA

A dramatic visualization of the interspersed sequence organization of egg $p(A)^+$ RNA is presented in Fig. 2. These electron micrographs illustrate the multi-stranded branched structures formed when $p(A)^+$ RNA molecules are renatured. The RNA was first fully denatured, then incubated to an equivalent C_0t of 600 M s in a buffered formamide medium and spread for electron microscopy, as described in the legend to Fig. 2. Almost no complicated structures, such as those shown, were observed in control samples spread immediately after denaturation ($C_0t < 2\times10^{-3}$ M s).

Interpretation of the structures shown in Fig. 2 is greatly assisted by the previous observation[5] that both complements of each repeat sequence are represented in sea urchin egg RNA, as in nuclear RNAs[4]. This is almost certainly not due to symmetrical transcription but to the presence of RNA molecules deriving from different transcription units orientated oppositely with respect to the repeat sequence. In contrast, all single-copy sequences so far analysed in sea urchin egg or nuclear RNAs are asymmetrically represented. This includes a number of specific sequences complementary to cloned probes (ref. 15 and unpublished data), as well as the total single-copy sequence sets of nuclear RNA[16]. With this background, it is clear that the multi-stranded structures shown in Fig. 2 are networks consisting of several individual long $p(A)^+$ RNA molecules held together by renatured complementary short repeat duplexes. The structures shown bear a strong resemblance to the structures formed when DNA from an animal displaying short-period repetitive sequence interspersion is renatured at low C_0t (ref. 17). RNA networks held together by renatured interspersed repeats were described previously by Federoff *et al.*[18], who observed them in HeLa cell nuclear RNA.

About 65% of the total contour length of the $p(A)^+$ RNA in a random sample studied (1.2×10^6 nucleotides) is included in branched structures displaying four or more ends, and apparently composed of two or more molecules. This should approximately estimate the mass fraction of $p(A)^+$ RNA-bearing repeats, since most of the RNA contour length appears to consist of single-stranded regions. Although it is impossible to interpret most of the RNA complexes unambiguously, some qualitative implications follow from their general structure. The presence of complementary repeat sequence transcripts previously observed in total egg RNA is seen to be a property of the $p(A)^+$ RNA. Over two-thirds of the molecules participating in intermolecular duplexes were present in structures displaying six or more ends, and therefore consisting of at least three

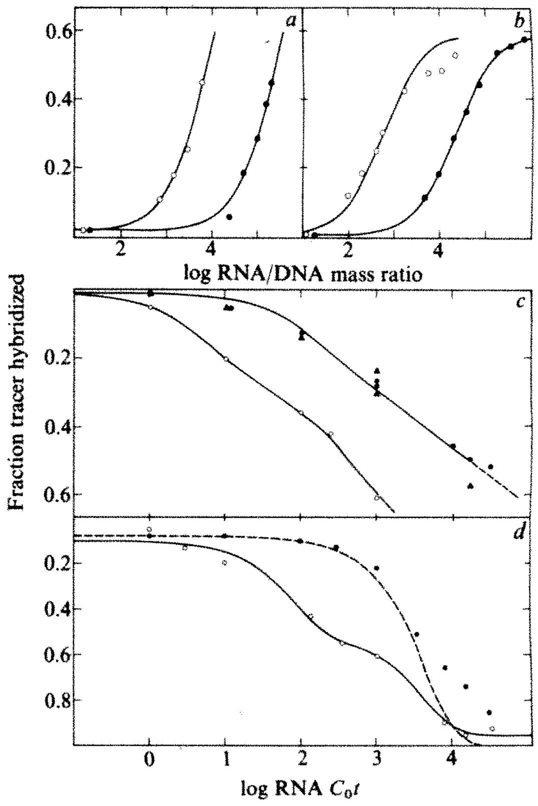

Fig. 1 Distribution of repetitive and single-copy sequences in egg $p(A)^+$ RNA and $p(A)^-$ RNA fractions. Total egg RNA was isolated[35] and fractionated on oligo(dT)-cellulose[40]. The RNA which bound consecutively on three passes was the $p(A)^+$ RNA fraction (1.5% of total egg RNA). RNA which repeatedly failed to bind was the $p(A)^-$ RNA fraction (98%). All RNAs were partially hydrolysed with alkali to about 1,000 nucleotides before hybridization. *a*, Titration of $p(A)^+$ and $p(A)^-$ RNA with the cloned repetitive-sequence, CS2109B[24]. The repetitive sequence cloned in plasmid CS2109B was excised with *Eco*RI, 5′ end-labelled with ^{32}P and strand separated[4]. Excess lower strand tracer was hybridized to termination with increasing amounts of $p(A)^+$ (○) or $p(A)^-$ (●) RNA. All hybridization reactions described here were assayed by hydroxyapatite binding, unless otherwise noted. The curves represent least-squares solutions to the form for the titration reactions given in equation (2) of Scheller *et al.*[4]. The specific fraction of $p(A)^+$ RNA consisting of CS2109B transcripts was 1.3×10^{-4}, and for $p(A)^-$ RNA the fraction was 4.1×10^{-6}. *b*, Titration of $p(A)^+$ RNA and $p(A)^-$ RNA with the upper strand of the cloned repetitive sequence CS2108[23]. The specific RNA fractions measured are 1.8×10^{-3} for $p(A)^+$ RNA and 4.7×10^{-5} for $p(A)^-$ RNA. *c*, Hybridization of excess $p(A)^+$ RNA (○), $p(A)^-$ RNA (●) or total egg RNA (▲) with repetitive ^3H-DNA tracer representing most of the short repeats in the genome. This tracer was prepared, as previously described[5], by reassociating sea urchin ^3H-DNA fragments of average length 3,300 nucleotides to C_0t 40 M s, digesting with S_1 nuclease, binding to hydroxyapatite, and fractionating according to molecular size on a Sepharose CL-2B column. The resulting short-repeat tracer displayed a weight-average length of 300 nucleotides. Hybridization was at 50 °C in 0.12 M phosphate buffer, *p*H 7.0. The data were fitted assuming second-order kinetics[4,5] with two kinetic components, but since the reactions are not terminated, only the faster component of each reaction, representing the more prevalent repeat transcripts, is meaningful. A fast component terminating at 30% hybridization was arbitrarily selected for analysis. The observed rate constants for this component are: $p(A)^+$ RNA, $k = 1.54\times10^{-1}\ M^{-1}\ s^{-1}$; total egg RNA or $p(A)^-$ RNA, $k = 4.6\times10^{-3}\ M^{-1}\ s^{-1}$. *d*, Hybridization of excess $p(A)^+$ RNA (○) or $p(A)^-$ RNA (●) with ^3H-labelled eDNA tracer. The eDNA tracer was prepared by enriching for the fraction of total single-copy ^3H-DNA that hybridizes with total egg RNA (about 3%). This particular eDNA tracer hybridized to an extent of 45% with total egg RNA and was thus about 15-fold purified relative to the starting single-copy DNA. Reactions with $p(A)^+$ and $p(A)^-$ egg RNAs have been normalized to the 45% terminal value. The dashed line indicates the kinetics of the reaction of eDNA with total egg RNA, that is, a single pseudo-first-order kinetic component with a rate constant of $2.3\times10^{-4}\ M^{-1}\ s^{-1}$. This rate was previously determined with several eDNA preparations[12] (see also Fig. 6*a*). The reaction with $p(A)^+$ RNA is heterogeneous and is fitted by two components (solid line), a fast component representing 41% of the tracer, with a rate constant of $1.2\times10^{-2}\ M^{-1}\ s^{-1}$, and a slow component representing 43% of the tracer, with a rate constant fixed at $2.3\times10^{-4}\ M^{-1}\ s^{-1}$. Comparing these rate constants to the rate constant for total egg RNA, we calculate that the fast component represents sequences 75% of whose transcripts are recovered in the $p(A)^+$ RNA fraction, while the slow component represents sequences that are mainly (>95%), though not exclusively, confined to the $p(A)^-$ RNA fraction. Note that the sequence concentration of almost half of the single-copy species is lower in the $p(A)^-$ RNA than in total egg RNA. These are presumably the species predominantly found in the $p(A)^+$ RNA fraction.

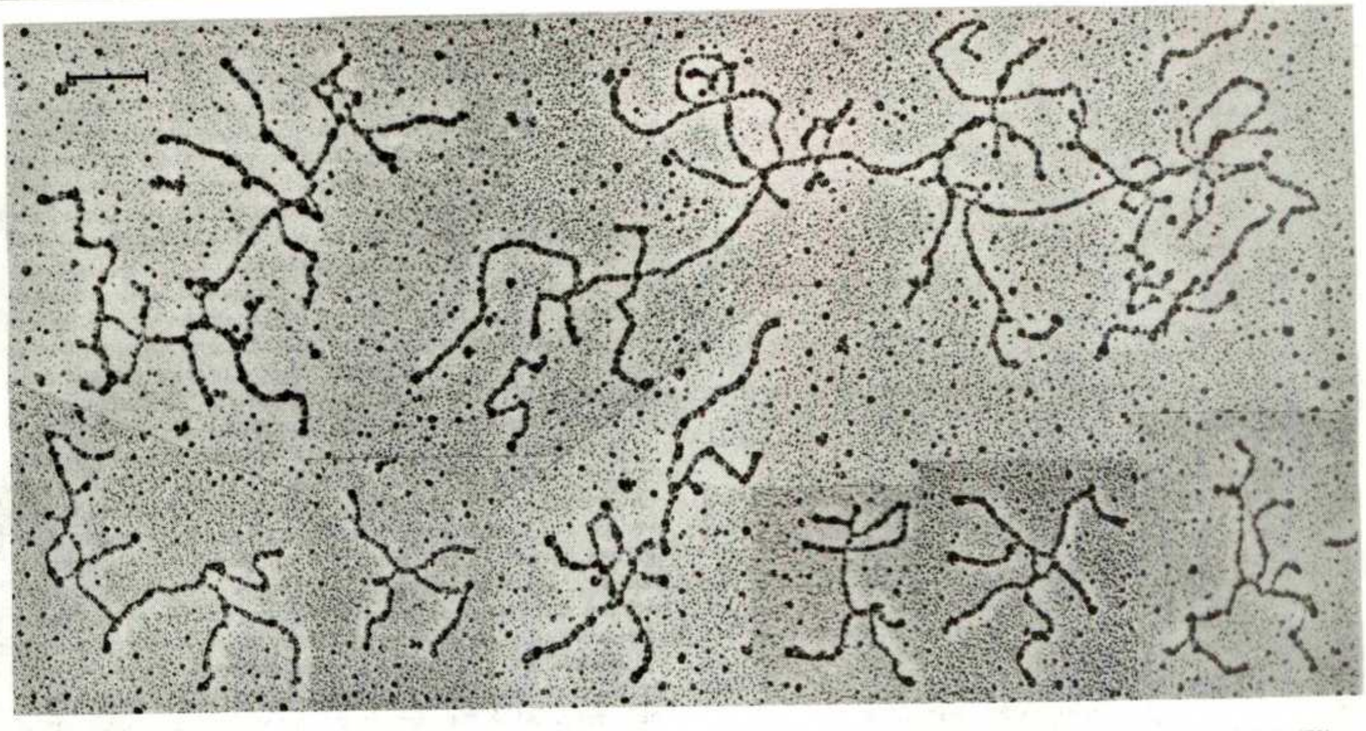

Fig. 2 Electron microscopy of multimolecular structures formed by renaturation of egg p(A)$^+$ RNA. Total p(A)$^+$ egg RNA was denatured at 70 °C in 67% formamide, 0.3 M NaCl, 0.01 M PIPES (*p*H 6.5), 10^{-4} M EDTA for 1 min, then incubated at 30 °C in 58% formamide, 0.75 M NaCl, 0.025 M PIPES (*p*H 6.5), 10^{-4} M EDTA, to equivalent C_0t 600 M s. The RNA was then diluted and spread for electron microscopy[41] from a hyperphase of 80% formamide, 0.1 M Tris (*p*H 8), 5 mM EDTA and 100 μg ml^{-1} cytochrome *c*, at 24 °C. Many multimolecular RNA structures, including large networks, were observed. The montage shown includes several relatively simple examples of such structures. The bar represents a single-strand RNA length of 1,000 nucleotides, estimated from circular single-stranded ΦX174 DNA included on the same grids, and including a 10% correction for the difference in linear densities of single-stranded RNA and DNA in these spreading conditions[42]. To estimate the fraction of RNA in multimolecular structures, random areas of the grid were photographed, and the total contour length of each structure was measured. The structures measured had a total contour length of 1.2×10^6 nucleotides, of which 65% was contained in structures having four or more discernible ends and judged to consist of two or more RNA molecules. Sea urchin rRNA did not form networks when incubated to the same C_0t and spread in identical conditions. When the p(A)$^+$ RNA was spread in the same conditions following denaturation ($C_0t < 2 \times 10^{-3}$ M s), no networks were observed, and less than 4% of the RNA length was in structures containing possible intermolecular duplexes. The denatured p(A)$^+$ RNA had a weight-average length of 5,000 nucleotides, and a number-average length of 3,400 nucleotides, based on a sample of 187 randomly selected molecules. Size determinations by agarose gel electrophoresis in the presence of methyl mercuric hydroxide[43] were consistent with these values.

molecules. It follows that many p(A)$^+$ RNA molecules bear more than one repeat sequence element. Otherwise, almost all renatured structures would include only two molecules and very large networks such as some of those shown in Fig. 2 would never have formed. Another general implication is that most of the length of those p(A)$^+$ RNA molecules which contain repetitive sequence elements consists of single-copy sequence transcript. This is demonstrated directly in the next section.

Interspersion of repetitive and single-copy sequences in egg p(A)$^+$ RNA

To examine the sequence organization of p(A)$^+$ RNA molecules containing repeat transcripts, it was necessary to purify these molecules with respect to the remainder of the RNA. The following strategy proved effective. Egg p(A)$^+$ RNA was labelled *in vitro* with ^{125}I (refs. 19–21), and hybridized with excess repetitive DNA which had previously been mercurated (Hg-DNA)[22]. Details are given in the legend to Fig. 3. Excess non-mercurated sea urchin ribosomal DNA (rDNA) was added to compete out the hybridization of contaminating ^{125}I-rRNA, which amounted to 1–5% of the various ^{125}I-p(A)$^+$ RNA preparations. After denaturation, the reaction mixtures were incubated to C_0t 50 M s with respect to the repetitive Hg-DNA, and fractionated on a sulfhydryl–agarose (SH–agarose) column. RNA molecules hybridized to the repetitive DNA are bound to this column, while non-hybridized RNA flows through. When mixed with the Hg-DNA (denatured or native) but not permitted to anneal, less than 1% of the ^{125}I-p(A)$^+$ RNA bound to the SH–agarose column. This background is somewhat lower than is obtained with the urea–phosphate hydroxyapatite-binding procedure[23] for trapping RNA hybrids formed with excess DNA. Control experiments showed that the same amount of hybrid was recovered with the SH–agarose Hg-DNA procedure, as by the urea–phosphate hydroxyapatite-binding method.

The kinetics of the hybridization reaction between the ^{125}I-p(A)$^+$ RNA and the repetitive Hg-DNA are illustrated in Fig. 3. To provide relative kinetic standards, Fig. 3 includes reactions of a genomic ^{3}H-DNA repeat tracer and of a single-copy ^{32}P-DNA tracer with the same Hg-DNA driver. The reaction of the ^{125}I-p(A)$^+$ RNA occurs at approximately the same rate as the reaction of the repeat DNA tracer. As expected, single-copy sequences are more than 10-fold reduced in concentration in the repetitive Hg-DNA driver compared to whole DNA. There is no reaction whatsoever of the ^{32}P-DNA single-copy tracer until $C_0t > 10^2$. Therefore, the ^{125}I-p(A)$^+$ RNA molecules which hybridize with the Hg-DNA at C_0t 10^{-2}–C_0t 10^2 M s (Fig. 3) must contain repeat sequences. The kinetics exclude the possibility that the trapped RNA molecules were bound by virtue of hybridization with residual single-copy sequences contaminating the repetitive Hg-DNA driver. Furthermore, when the bound RNA is eluted and again reacted with the repetitive Hg-DNA driver, the kinetics observed are consistent with those in the initial reaction.

Although binding the p(A)$^+$ RNA–Hg–DNA hybrids to SH–agarose effectively isolates molecules which include repeat transcripts, the yield of the procedure is low. After hybridization, only 16–19% of the ^{125}I-p(A)$^+$ RNA binds to the SH–agarose column. In the presence of excess sea urchin rDNA, the fraction of ^{125}I-RNA bound falls slightly, to 11–16%. Several factors suggest that this value seriously underestimates the true fraction of p(A)$^+$ RNA molecules which include repeat-sequence elements: (1) The repetitive DNA driver was prepared by incubation of the starting DNA to C_0t 50 M s resulting in under-representation of repeat sequences whose frequency of occurrence is less than 10–20 copies per genome. (2) The

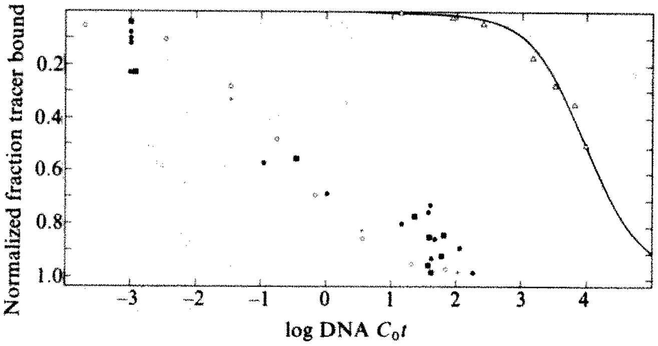

Fig. 3 Kinetics of hybridization of ^{125}I-p(A)$^+$ RNA with excess mercurated repetitive DNA. ^{125}I-p(A)$^+$ egg RNA was hybridized with a 100- to 1,000-fold excess of mercurated repetitive sea urchin DNA and hybridization was assayed by binding to SH–agarose. To facilitate kinetic comparisons, hybridization values are normalized to the maximal extent of reaction in each curve. All reaction mixtures were denatured in 65–75% formamide, 0.3 M NaCl at 75–80 °C, then incubated in 50% formamide, 0.75 M NaCl, 0.025 M PIPES (*p*H 6.5), 10^{-4} M EDTA, 0.1% SDS and 5×10^{-5} M NaCN, at 30 °C. Binding to SH–agarose[44] was performed in 0.5 M NaCl, 0.01 M Tris (*p*H 7.5), 10^{-3} M EDTA, 0.05% SDS, and the bound nucleic acids were eluted with the same buffer containing 0.1 M β-mercaptoethanol. Repetitive sea urchin DNA was prepared by S_1 digestion of total DNA after reassociation to C_0t 50 M s (refs 45 and 46), and the repetitive DNA was covalently mercurated[22]. 85–90% of native or denatured mercurated DNA could be bound to SH–agarose. The abscissa indicates equivalent C_0t values[45], including an estimated 2.5-fold rate retardation due to hybridization in 50% formamide[47]. ■, hybridization of ^{125}I-p(A)$^+$ RNA in the presence of excess non-mercurated rDNA competitor (normalized from a 13% terminal value); ●, the same, but without rDNA competitor (normalized from a 20% terminal value); +, re-reaction of hybridized ^{125}I-p(A)$^+$ RNA with more repetitive Hg-DNA driver, plus rDNA competitor (normalized from a 35% terminal value). For comparison the hybridization kinetics of short repetitive ^{3}H-DNA (○) (normalized from a 90% terminal value), and single-copy ^{32}P-DNA tracer (△) (normalized from a 95% terminal value obtained with unfractionated DNA driver) are shown, with the same repetitive Hg-DNA driver. The latter two reactions were assayed by binding to hydroxyapatite.

reaction criterion (50% formamide, 0.75 M NaCl at 30 °C) probably precludes duplex formation within the less closely related classes of repeat sequences found in the sea urchin genome[24]. (3) The p(A)$^+$ RNA was unavoidably subjected to some strand scission during iodination. The weight-average length of the total iodinated p(A)$^+$ RNA was about 1,400 nucleotides, as measured on denaturing formaldehyde–sucrose gradients[25]. ^{125}I-p(A)$^+$ RNA which had been hybridized with Hg-DNA, bound to SH–agarose, and eluted displayed the same length distribution. While the hybridization procedures thus result in no further strand scission, the fragment length of the p(A)$^+$ RNA after iodination is less than one-third its starting length. Unless all repeat sequences in the RNA are distributed less than 1,400 nucleotides apart, this amount of breakage would have resulted in a decrease in the fraction of p(A)$^+$ RNA bound after hybridization with the repetitive Hg-DNA. (4) The SH–agarose column binds only about 40% of the available repetitive RNA–DNA duplexes. As shown in Table 1, when RNA that fails to bind after reaction with Hg-DNA is re-hybridized, another 8–13% can be bound. When once-bound RNA molecules, all of which must contain a hybridizable repeat sequence, are eluted and re-hybridized, only 40% bind to a second SH–agarose column. A probable explanation, according to experiments not shown here, is that duplexes between mercurated and non-mercurated nucleic acids bind with less than 50% efficiency to SH–agarose. This phenomenon was also reported earlier by Nguyen-Huu *et al*[26]. Using the data of Table 1, we estimate that about 35% of 1,400 nucleotide p(A)$^+$ RNA fragments actually contained recognizable RNA–DNA hybrids (that is, 15% initial binding normalized for a 40% SH–agarose binding efficiency). This estimate is still two-fold below that obtained from our electron microscopic observations. The most likely explanation is the difference of over threefold in RNA fragment length in the two experiments. In addition, more repeat duplexes may have survived the conditions of the electron microscope experiment than could be recovered as Hg-DNA–RNA hybrids, due to the relatively high stability of RNA–RNA duplexes in formamide media.

The repetitive and single-copy sequence content was measured in a sample of ^{125}I-p(A)$^+$ RNA which had been twice reacted with the repeat Hg-DNA driver, in the presence of rDNA competitor, and bound to SH–agarose (preparative data are shown in Table 1). After elution, the RNA was hybridized with excess whole sea urchin DNA, and the ribonuclease resistance of the ^{125}I-RNA was determined as a function of DNA C_0t (refs 23, 27). Data are shown in Fig. 4. Least-squares analysis of this reaction indicates that 85–90% of the mass of the selected ^{125}I-RNA is single-copy sequence transcript. However, these single-copy sequences must be linked to repetitive sequences, since every RNA molecule in the selected ^{125}I-RNA fraction contains at least one repeat-sequence element.

The repetitive sequences in the bound p(A)$^+$ RNA are generally short, although a small fraction of the RNA could consist entirely of repeat transcripts. Figure 4 suggests that the average 1,400-nucleotide ^{125}I-RNA fragment bound to SH–agarose includes less than 200 nucleotides of repetitive sequence. In other experiments ^{125}I-p(A)$^+$ RNA was reacted with the Hg-DNA, bound to SH–agarose and the hybrid molecules were eluted and digested directly with ribonuclease. Only 8–12% of the ^{125}I-RNA was resistant, again indicating that there are no more than 170 nucleotides of repeat sequence on the average RNA fragment in this fraction. It is unlikely that a significant amount of hybridized repetitive RNA was rendered soluble in trichloroacetic acid (TCA) by the ribonuclease digestion since the amount of resistant RNA was the same when the assay was carried out at 0 °C as at 37 °C. It is nonetheless

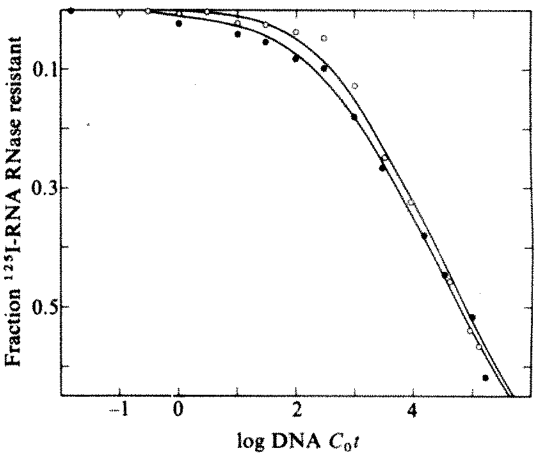

Fig. 4 Repetitive and single-copy sequence content of repeat-containing egg p(A)$^+$ RNA. A fraction of p(A)$^+$ RNA, consisting of transcripts containing repeated sequences, was selected by hybridization with repetitive Hg-DNA and chromatography on SH–agarose (see text). Hybridization of contaminating ^{125}I-ribosomal RNA was blocked by competition with non-mercurated cloned sea urchin ribosomal DNA. This selection procedure was then repeated to assure purity (see Table 1). The final selected ^{125}I-RNA (●), or total ^{125}I-p(A)$^+$ egg RNA (○), was then reacted with a 10^5–10^6-fold excess of total sea urchin DNA. Hybridization was assayed by digestion with 10 μg ml^{-1} ribonuclease A for 1 h at 37 °C in 0.24 M phosphate buffer (*p*H 6.8), 10^{-3} M EDTA, followed by precipitation with cold 10% TCA and collection on Whatman GF/C filters. Hybridized RNA sequences are resistant to digestion in these conditions, while single-strand regions are hydrolysed. To estimate the fractions of ^{125}I-RNA hybridizing with repetitive or with single-copy sequences in the driver DNA the data were fitted using a function that takes into account the retarded hybridization of RNA tracers[48], as well as the effects of a nuclease-resistance assay on the observed kinetics[49–51]. The fraction of the selected ^{125}I-RNA hybridizing as a repetitive component appears to be between 10% and 15%, depending on the allowed average repetition frequency. A reasonable estimate, assuming an average frequency of 100 copies per genome, suggests that 89% of the selected RNA fraction consists of single-copy sequence transcript, and 11% of repeated-sequence transcript, while the total p(A)$^+$ RNA is 93% single-copy sequence transcript and 7% repeated-sequence transcript. These solutions are indicated by the solid lines shown. The total ^{125}I-p(A)$^+$ RNA preparation contained about 1% ribosomal RNA measured by hybridization with cloned ribosomal DNA.

Table 1 Fraction of ^{125}I-p(A)$^+$ RNA binding to SH–agarose after hybridization with excess mercurated repetitive DNA

	% bound			
		Re-reaction of bound fraction		Re-reaction of unbound fraction
Experiment	First reaction +rDNA	+rDNA	−rDNA	+rDNA
1	15	42	40	8
2	16	30,35	40	13

Hybridization and assay conditions are described in the legend to Fig. 3. All hybridizations were carried out at DNA C_0t 50 M s. In each experiment, egg ^{125}I-p(A)$^+$ RNA was hybridized with a 100-fold mass excess of mercurated repetitive DNA, in the presence of a large sequence excess of non-mercurated cloned sea urchin rDNA[39]. The reaction mixtures were then chromatographed on an SH–agarose column. Aliquots of the bound fraction were denatured and re-reacted with additional mercurated repetitive DNA, plus or minus rDNA competitor, as indicated. The unbound fraction was similarly re-reacted in the presence of rDNA competitor.

possible that the average length of the repeat sequences could be somewhat greater than 170–200 nucleotides. In any case we conclude that at least 35% (and perhaps twice this fraction) of sea urchin egg p(A)$^+$ RNA has an interspersed sequence organization, in which short repetitive sequences are covalently associated with longer single-copy sequence transcripts.

Complexity of single-copy sequences linked to repeats in egg RNA

In this section, we demonstrate that the interspersed egg RNAs include most of the diverse species of single-copy sequence transcript found in the egg, and therefore, most of the diverse maternal mRNAs. To measure the complexity of the single-copy sequence transcripts associated with repeats in the egg RNA, we prepared a selected fraction of total egg RNA in which the interspersed RNA molecules were relatively concentrated. We then hybridized this fraction with an eDNA tracer. Hough-Evans *et al.*[12] showed earlier that at least 75% of the single copy sequence represented in total egg RNA is included in the mRNA of early embryo polysomes. The eDNA tracer is therefore a probe for the complex assemblage of single-copy sequences comprising the maternal message set stored in the sea urchin egg.

The RNA fraction required for this complexity measurement was obtained by hybridizing total egg RNA with repetitive Hg-DNA, followed by chromatography on SH–agarose. The egg RNA/Hg-DNA mass ratio was sufficient to permit hybridization of most of the diverse repeat transcripts, but very little of the egg rRNAs or tRNAs (see legend to Fig. 5). After hybridization, 2.2% of the total egg RNA bound to the SH–agarose column. The Hg-DNA was eliminated by DNase treatment, and a measurement was made of the enrichment for repeated sequence transcripts actually obtained in the fractionation. Thus, the concentration of transcripts complementary to two cloned repetitive sequences was determined by titration with the selected RNA fraction. Figure 5 shows that transcripts complementary to the repeat sequence of clone CS2109B are present at an 11-fold higher concentration in this RNA fraction than in total egg RNA. Similarly, the repeat sequence of clone CS2111 (ref. 24) is nine times more concentrated in the selected RNA fraction. We expect, therefore, that single-copy sequence transcripts linked to repeats will also be concentrated in the selected RNA fraction by a factor of about 10, with respect to total egg RNA.

The kinetics of reactions between a ^{32}P-eDNA tracer and the selected RNA fraction, as well as the reaction of the ^{32}P-eDNA with total egg RNA, are shown in Fig. 6*a*. This tracer contained no detectable repetitive-sequence component (data not shown). Both of the eDNA hybridization reactions in Fig. 6*a* terminate at about 85% of the tracer bound. Therefore, the selected RNA fraction includes essentially all the diverse single-copy sequences in total egg RNA. The experiment clearly shows that the single-copy sequence transcripts driving the eDNA reaction are concentrated in the selected RNA fraction. Least-squares solutions to the kinetic data indicate that 70–80% of the reaction is accelerated 10-fold compared to total egg RNA, while the remaining 20–30% is accelerated 2-fold. It follows that at least 70–80% of the diverse single-copy sequences in egg RNA exist on transcripts also containing repeated sequences. Since the large majority of the same single-copy sequences are represented in polysomal mRNA after fertilization, most, if not all, of the interspersed egg RNAs are maternal messages. Furthermore, interspersed transcripts are the major form of these maternal mRNA species, rather than a minor variant. If, for example, only 25% of the transcripts of a particular single-copy sequence contained a repeat sequence, a 10-fold enrichment for that repeat would result in only a 2.5-fold enrichment for the single-copy sequence. It is possible that the 20–30% of single-copy sequences that appear to be less enriched in the selected egg RNA fraction reside on transcripts which lack repeats. Alternatively, these sequences might simply represent regions of transcripts that are relatively distant from repeats and are often separated from them by a strand scission.

Interspersed repetitive sequences exist in prevalent as well as rare or complex-class maternal messages. This was shown by titration experiments with a cloned cDNA fragment, SpG30, which represents a highly prevalent egg p(A)$^+$ mRNA. There are about 2×10^5 molecules of this RNA per egg. The cloned SpG30 fragment is about 700 nucleotides long and consists entirely of single-copy sequence[13]. Figure 6*b* illustrates titration measurements of the sequence concentration of transcripts complementary to the strand separated SpG30 probe in total egg RNA, and in the repeat-enriched selected RNA fraction. Like most rare single-copy transcripts, this highly prevalent single-copy sequence is also about 10-fold more concentrated in the repeat-enriched RNA fraction. A repetitive sequence therefore must be located somewhere on the SpG30 transcript.

Discussion

We have shown that a substantial fraction of the heterogeneous RNA in the sea urchin egg, including the p(A)$^+$ RNA, consists of short repetitive sequence transcripts covalently linked to longer single-copy sequences. While these interspersed transcripts have many properties that identify them as maternal messages, we have not demonstrated that they actually function as messages. However, most of the diverse message sequences in the egg are found on molecules which display an interspersed sequence organization. In addition, essentially all of the mass of the heterogeneous repeat-sequence transcripts in the egg[5] can

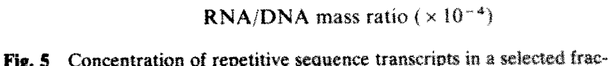

Fig. 5 Concentration of repetitive sequence transcripts in a selected fraction of egg RNA. To yield a fraction enriched for transcripts containing repeated sequences, 1 mg of unlabelled total egg RNA plus 8µg of ^{125}I-labelled total egg RNA was hybridized with 1 mg of repetitive Hg-DNA. This is a sufficient DNA/RNA ratio to provide a DNA sequence excess for any repeat present in more than 20 copies per genome and contained on fewer than 2×10^5 transcripts per egg. The reaction mixture was incubated to Hg-DNA C_0t 50 M s, then fractionated on an SH–agarose column, as described in Fig. 3. The bound fraction was eluted with 0.1 M β-mercaptoethanol, and the repetitive Hg-DNA was completely removed by DNase digestion. Two ^{32}P-labelled cloned repetitive sequences were then titrated with total egg RNA and with the selected RNA fraction. *a*, Titration of the repeat sequences from clone CS2109B, lower strand (■), and clone CS2111, lower strand (●) with total egg RNA. *b*, Titration of the same two repeat sequences with the selected repeat-enriched RNA. The complementary RNA fractions are: CS2109B, 2.1×10^{-6} of total egg RNA and 2.3×10^{-5} of repeat-enriched RNA; CS2111, 1.5×10^{-5} of total egg RNA and 1.4×10^{-4} of repeat-enriched RNA.

be accounted for as interspersed RNA molecules. The precise physical organization of these maternal RNAs is not yet apparent. This will require further analysis of individual transcripts using cloned DNA probes. We know, however, that the repetitive sequence elements are relatively short, averaging only 150–200 nucleotides. According to primary sequence data, six out of eight cloned repeat elements contain translation stop codons in all reading frames[3], and this observation suggests that the repeats may be located elsewhere than in translated regions of the message. It is also likely that more than one repeat-sequence element exists on many RNA molecules. A possibility not yet excluded is that the repeat-sequence elements are removed by cytoplasmic processing events before polysomal translation. It is also possible, if unlikely, that only the minor fraction of egg transcripts which lack repeats serve as maternal messages.

Is interspersed sequence organization a feature peculiar to sea urchin maternal RNAs? Earlier studies on the newly synthesized polysomal mRNA of gastrula stage sea urchin embryos failed to reveal a significant fraction of message containing linked repetitive and single-copy sequences[23,28]. There have been several reports on the sequence organization of messages from other animal cell types (see, for example, refs 29–32). With the aid of cloned probes, Firtel and his associates recently clearly demonstrated that short repeat-sequence elements exist on certain predominantly single copy *Dictyostelium* mRNAs[33,34]. Re-examination of sea urchin gastrula mRNA by the methods described here, as well as those previously used reveals a small fraction of polysomal mRNAs which contain interspersed repeats (unpublished data). However, a major distinction exists in the amount of repetitive-sequence transcript in egg maternal RNA as opposed to gastrula polysomal mRNA. While the egg contains many highly prevalent repeat transcripts[5], the gastrula mRNA seems to contain few if any repeat-sequence transcripts of equally high prevalence. The only highly prevalent interspersed repeat transcripts observable in the sea urchin gastrula are found in the nucleus, as concluded earlier by Scheller *et al.*[4]. The process by which this intracellular distribution of repeat transcripts is achieved during development is unknown, as is its functional significance.

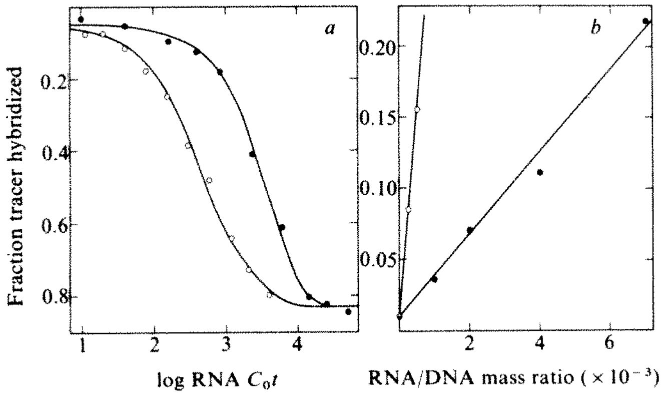

Fig. 6 Complexity of single-copy sequence transcripts included in the selected repeat-enriched RNA fraction. *a*, Hybridization of an eDNA ^{32}P-labelled tracer containing all the single-copy sequences represented in total egg transcripts with excess total egg RNA (●) or with the selected repeat-enriched egg RNA fraction (○) described in Fig. 5. The ^{32}P-labelled eDNA tracer was prepared, as previously described[12], by hybridizing total single copy ^{32}P-DNA with total egg RNA and purifying the hybridized fraction. The eDNA preparation used in this experiment was about 30-fold enriched for egg RNA sequences relative to the starting single-copy ^{32}P-DNA preparation. Hybridization was dependent on added RNA, and hybrids were sensitive to RNase digestion in low salt[52]. The curve shown for the total egg RNA reaction describes a single pseudo-first-order kinetic component with a rate constant of $2.3\times10^{-4}\ M^{-1}\ s^{-1}$. In the kinetic solution shown here for the reaction with the repeat-enriched RNA fraction two components were assumed. The rate constant for the faster component was fixed at $2.3\times10^{-3}\ M^{-1}\ s^{-1}$ or 10 times the rate constant obtained with total egg RNA so as to estimate the fraction of single-copy sequences enriched to the same extent as repeats. This component included 70% of the reaction, while 30% displays a rate constant of $4.1\times10^{-4}\ M^{-1}\ s^{-1}$. *b*, Titration of the ^{32}P-labelled single-copy DNA sequence of clone SpG30, upper strand, with total egg RNA (●) or with the repeat-enriched egg RNA fraction (○). The complementary fraction of total egg RNA was 3.0×10^{-5}, while the complementary fraction of repeat-enriched RNA was 2.9×10^{-4}.

Our most important conclusion pertains to the sequence organization of the sea urchin genome and its possible function. We found earlier[28] that the single-copy sequences represented in embryo mRNA tend to be located non-randomly, close to interspersed repetitive sequences in the genome. Our present data require the further conclusion that most of the structural genes represented in egg RNA belong to sets, each of which is defined by the presence of homologous sequences of a given repeat family. This can be seen as follows: According to previous measurements, transcripts of 10–20% of the diverse repetitive sequence families in the genome, or 500–1,000 different sequence families, are prevalent in the egg RNA[5]. About 10^5 transcripts represent each of these prevalent repetitive sequence families per egg, and together these account for ⩾90% of the mass of interspersed repeat transcripts. No more than a few per cent of the mass of the repeat transcripts are accounted for by rare repeat sequences, that is, those represented in only 10^3–10^4 copies per egg[5]. On the other hand, 60–80% of the maternal mRNA in the egg consists of rare, complex-class single-copy sequence transcripts (refs 7, 12 and unpublished data). Most of these complex-class transcripts are covalently linked to repeats, according to the experiment of Fig. 6*a*, and most of the repeats must belong to the prevalent repeat-transcript class[5]. Since the complexity of the egg single-copy sequence set is 3.7×10^7 nucleotides[12,35], whereas there are only a few hundred kinds of prevalent repeat transcripts, a majority of these repetitive-sequence families must be represented on many (probably between 10 and 50) different rare messages. It follows that the prevalent repeat transcripts belonging to each family must have derived from many distinct transcription units, each including a different single-copy gene (or a few such genes). Thus, both the structural genes expressed during oogenesis and the many thousands of mRNA species produced by their transcription are distributed among several hundred sets, according to the particular repetitive-sequence family represented on each mRNA molecule. A similar organization has been observed in *Dictyostelium*[33,34], where two prevalent repeat transcripts each appear to be associated with 50–100 different rare mRNAs.

The organization of structural genes in sets or 'gene batteries', each associated with a specific repeat family (or families), has been proposed in models for regulation of gene expression[36,37]. It was envisioned that the shared repeats of each battery provide the physical basis for coordinate control of its expression. It is easy to see that the distribution of only 10–20% of the different repeat sequences in the genome among the more than 10^4 single copy message species in the egg implies a non-random arrangement of certain repetitive sequences among those genes which are expressed during oogenesis. However, there is no evidence regarding the actual function, if any, of the transcribed interspersed repeats. Their presence in the maternal RNA provides an unexpected opportunity for further examination of the physiological meaning of genomic sequence interspersion. Among the functions which might be envisioned for these repeat transcripts are suppression of mRNA utilization before fertilization, translational control affecting the timing of utilization of specific mRNA sets following fertilization, control of the differential distribution of maternal mRNAs to various regions of the early embryo, or sites for specific RNA processing events before translation. Alternatively, they might be remnants of transcriptional or post-transcriptional regulatory signals[36,37], incompletely removed from germinal vesicle precursors. A different possibility is that some of the maternal repeat transcripts could serve in a regulatory capacity in early embryo nuclei, where they might be involved in imposing initial patterns of gene expression which are similar to those in effect during oogenesis[12,35,38].

We thank Drs William H. Klein and Richard H. Scheller for their assistance and Drs Richard Axel and Norman Davidson for critical reviews of the manuscript. This research was supported by NIH Grant HD-05753. R. J. B. is a staff member of the Carnegie Institution of Washington.

Note added in proof: The characteristics of sea urchin egg p(A)$^+$ RNA described here pertain as well to the p(A)$^+$ RNA of *Xenopus*, an anuran vertebrate. When p(A)$^+$ RNA from the unfertilized egg of *Xenopus* (obtained by Dr L. Dennis Smith) was renatured and spread for electron microscopy under the exact conditions of Fig. 2 (by M. E. Chamberlin), the following results were obtained. (1) RNA which was not permitted to anneal after denaturation displayed only occasional intrastrand foldback structures. (2) RNA renatured to C_0t 60 was largely involved in structures containing two to four molecules bound by short duplex regions. And (3), RNA renatured to C_0t 600 was largely included in complex multimolecular aggregates often containing more than 10 molecules.

Structure of a family of rat amylase genes

Raymond J. MacDonald*, Michael M. Crerar†, William F. Swain,
Raymond L. Pictet‡, Gilles Thomas‡ & William J. Rutter||

Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143

The sequences of two cloned rat pancreatic amylase cDNAs comprising 95% of the mRNA sequence are reported. Analysis of cloned rat genomic DNA fragments using cloned cDNA probes indicates that the rat genome contains multiple closely related amylase genes in which the cDNA sequences are distributed within a region 9 kilobases in length and are interrupted by at least seven intervening sequences.

α-AMYLASE confers on the cell or organism producing it the capacity to use polyglucosides with α-1,4 linkages (such as starch) as energy and carbon sources. The rat genome, like other mammalian genomes, contains multiple closely related amylase genes which are selectively expressed in a number of differentiated cells. Amylase is a major product of the pancreas and parotid glands, accounting for approximately 20% of the total protein[1,2], and is associated with the digestive functions of these tissues. Liver also produces amylase but in relatively low quantities[3]; it is a prominent source of serum amylase in the normal animal[3].

Because of its prominent functional role amylase has served as a specific marker of differentiation[4–9]. The synthesis of amylase is initiated in parotid and pancreas cells at different periods of embryological development according to the differentiative programmes of these cells[10]. The synthesis of amylase in pancreatic acinar cells is apparently dependent on insulin[11], and can be induced fourfold by glucocorticoids so that it represents more than 70% of the total protein synthesis[12]. The difference in amylase levels in pancreas, parotid and liver parallel the relative abundance of amylase mRNA in the tissue[13]. Thus it appears that amylase synthesis is largely regulated at the level of mRNA synthesis or degradation.

The results of a variety of studies suggest the amylases of pancreas, parotid and liver, though similar, are distinct proteins and are the products of at least three distinct genes. The amylases isolated from the pancreas and parotid are immunologically distinguishable and have clearly different peptide maps[14,15]. Immunological studies also suggest differences in the parotid and liver enzymes[16]. The melting profiles of complementary (c)DNA·RNA hybrids formed with pancreatic amylase cDNA indicate greater than 90% sequence homology between pancreatic, parotid and liver amylase mRNAs but also clearly distinguish the pancreatic mRNA from the parotid and liver mRNAs[13]. Preliminary evidence suggests differences between parotid and liver amylase mRNAs as well[13].

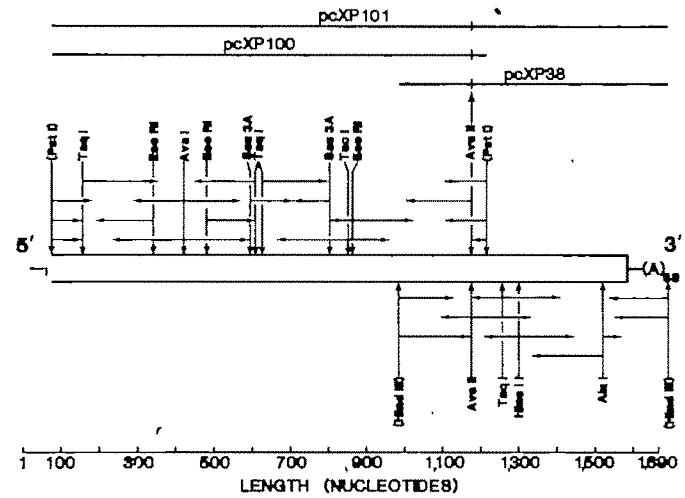

Fig. 1 Sequencing strategy for rat pancreatic amylase mRNA. The extent of the two double-stranded cDNA cloned sequences is discussed in the text. The direction of each sequencing reaction is shown by the horizontal arrows, starting at the restriction sites shown. (The number of bases determined in each reaction is indicated by the length of the arrows.) The 5′ end-labelled restriction fragments for sequencing were prepared from double-stranded cDNA separated from the pBR322 sequences. The internal *Hin*dIII site was derived from the *Hin*dIII restriction site linker added to the pcXP38 insert during the double-stranded cDNA cloning. The dotted line at the 5′ end indicates the uncloned portion of the mRNA.

In view of their common ancestral origin and their selective expression in differentiated cells, the amylase genes present an unusually favourable opportunity for analysis of structure–function relationships in eukaryotic genes. We describe here the nucleotide sequence of amylase mRNA derived from a nearly full-length cDNA cloned in bacteria. From this nucleotide sequence we have deduced the amino acid sequence of pancreatic amylase and certain characteristics of the amylase molecule.

Using the cDNAs as probes we have isolated genomic DNA fragments containing amylase genes. We present here the overall structure of the several amylase genes present in the rat genome.

Sequence of amylase cDNA

The details of molecular cloning of the population of predominant rat pancreatic mRNAs as cDNA and the identification of cloned sequences for a number of secretory enzyme mRNAs including amylase will be described in detail elsewhere[17]. Approximately 220 recombinant clones containing pancreatic amylase cDNA sequences have been identified among approximately 1,400 recombinant bacterial transformants. Restriction endonuclease analysis revealed two overlapping cDNA clones, designated pcXP38 and pcXP100, which contain cDNA inserts of 702 and 1,176 base pairs, respectively. These were sequenced by the method of Maxam and Gilbert[18], according to the sequencing strategy shown in Fig. 1. The sequence is given in Fig. 2. The pcXP38 cDNA insert contains a terminal poly(A) stretch of 68 residues and therefore encodes the 3′ end of the mRNA. The pcXP100 insert overlaps with 227 nucleotides at the 5′ end of the pcXP38 insert (Fig. 1); thus the total length of the mRNA sequence contained in the two plasmids is 1,615 nucleotides. The length of pancreatic amylase mRNA, estimated by agarose gel electrophoresis in the presence of methyl mercury[19], is 1,690±30 nucleotides[17] (average of 12 determinations) including an average poly(A) length of 65 nucleotides[8]. The sequence contained in the two cloned cDNAs therefore represents greater than 95% of the total mRNA sequence and lacks 75±30 nucleotides at the 5′ end of the mRNA.

The nucleotide sequence of the 227-base pair overlap common to both cloned cDNAs is identical at all positions except position 1,139 (Fig. 2) which is unambiguously T in pcXP38 and A in pcXP100. This discrepancy may have been introduced by the cloning procedures[20], or may reflect the cloning of two closely related, perhaps allelic, pancreatic amylase mRNAs.

Organization of the amylase mRNA sequence

The amino acid sequence of rat pancreatic amylase, derived solely from the nucleotide sequence of the mRNA, is given in Fig. 2. The amino acid sequence of the protein has not yet been determined, so comparison of independent amino acid and nucleotide sequences is not possible; however, the authenticity of the proposed reading frame and the consequent amino acid sequence is supported by the following criteria: (1) the reading frame shown is the only one without multiple termination codons; (2) the calculated molecular weight of the proposed amylase sequence, including amino-terminal residues, which probably correspond to a portion of the prepeptide, is 56,570. This is similar to the 58,000 molecular weight estimate for the rat pancreatic amylase precursor synthesized *in vitro*[5]; (3) the amino acid composition of the deduced sequence coincides with that reported for rat pancreatic amylase[17,21]. The fractions of aspartate plus asparagine (17%) and tryptophan (3.5%) are characteristically high for amylase[21] compared with the average for 314 proteins compiled by Dayhoff *et al.*[22]. The amino acid compositions of the multiple potential polypeptides predicted by each of the other two reading frames are dissimilar; (4) digestion of purified rat pancreatic amylase with phenylmethylsulphony fluoride (PMSF) treated carboxypeptidase A in the conditions described by Ambler[23] releases only leucine (data not shown), consistent with the carboxyl terminal dipeptide, Lys-Leu, predicted by the proposed coding sequence[24]; (5) the amino acid sequence is 76% homologous with the amino acid sequence of a number of unordered peptides that account for approximately 75% of the total sequence of porcine pancreatic amylase (provided by L. Paseno, B. Alandie, Y. Mazzei, D. Moinier, J. P. Bizzozero, M. Fougereau, Y. Chickeportiche and G. Marchis-Mouren). It is significant that porcine pancreatic amylase has a lower molecular weight than the rat enzyme by 3,000–5,000 (ref. 25) and has an isoelectric point of 5.4 (ref. 25), compared with 8.8–9.0 for rat pancreatic amylase[15]. Despite these differences the sequence homology between the two enzymes is high.

The amino-terminal portion of the predicted amino acid sequence for rat pancreatic amylase (Fig. 2) can be uniquely aligned with the partial amino-terminal sequence of rat parotid preamylase[26] so that seven of the nine identified residues in a region 27 residues long are congruent. This alignment suggests that the cDNA sequence lacks four-and-one-third codons or 13 coding nucleotides including the initial AUG but contains the carboxyl-terminal portion of the prepeptide. The entire coding region of rat pancreatic amylase mRNA is thus probably 1,551 nucleotides long, encoding 517 amino acids. The exact carboxyl terminus of the prepeptide, that is, the point of cleavage by a signal peptidase[27], cannot be located at this time because the amino terminus of the mature enzyme is acetylated and consequently has not been identified.

The single nucleotide discrepancy within the overlapping sequences of pcXP38 and pcXP100 (position 1,139) is silent with respect to the amino acid sequence since both of the alternative codons, AUA and AUU, specify Ile 379.

The length of the 5′-untranslated region, estimated to be 60±30 nucleotides, is within the range of other reported 5′-untranslated regions, that is, from 32 nucleotides in mouse β-globin mRNA[28] to greater than 112 nucleotides in the ACTH β-lipotropin mRNA[29]. In contrast, pancreatic amylase mRNA has a very short 3′-untranslated region relative to other eukaryotic mRNAs which have been characterized. The 3′-untranslated region of pancreatic amylase mRNA is only 35 nucleotides long whereas the reported lengths of 3′-untranslated regions in other mRNAs range from 57 nucleotides for rat insulin[30] mRNA to 950 nucleotides for mouse dihydrofolate reductase mRNA[31]. A short 3′-untranslated region is not a

Fig. 2 The nucleotide sequence of rat pancreatic amylase mRNA. The sequence was determined from the double-stranded cDNA inserts of pcXP38 and pcXP100 (Fig. 1) by the method of Maxam and Gilbert[18]. The predicted amino acid sequence is indicated. The divergent heptanucleotide sequence AAUUAAA is underlined. The single nucleotide discrepancy between the double strands of pcXP38 and pcXP100 is circled.

general feature of mRNAs encoding the pancreatic secretory proteins because the 3′-untranslated region of proelastase mRNA is 289 nucleotides long[17]. The short 3′-untranslated region requires that functionally important sequences near the 3′ end of amylase mRNA be either less than 35 nucleotides or contained in the coding region. The heptanucleotide, AAUUAAA is present in this region centred 23 nucleotides from the poly(A). This sequence appears to be the first detected variant of the hexanucleotide sequence, AAUAAA, found approximately 20 nucleotides from the poly(A) in every polyadenylated RNA sequenced to date. The variation of this sequence probably reflects a flexibility in the sequence requirement at this site rather than a modulation of some aspect of the metabolism of exocrine mRNAs since the hexanucleotide, AAUAAA, is conserved in proelastase mRNA[17]. Interestingly, the heptanucleotide AAUUAAA has also recently been found in anglerfish pancreatic somatostatin mRNA[32].

Structural domains in amylase

Several experimental observations suggest that the amylase molecule is arranged in two similar domains. Mammalian amylase can bind two molecules of the substrates glycogen[33] and maltotriose[34] and at least two molecules of the substrate analogue β-cyclodextran[35]. An endogenous protease[36,37] cleaves amylase into two polypeptides of approximately equal size

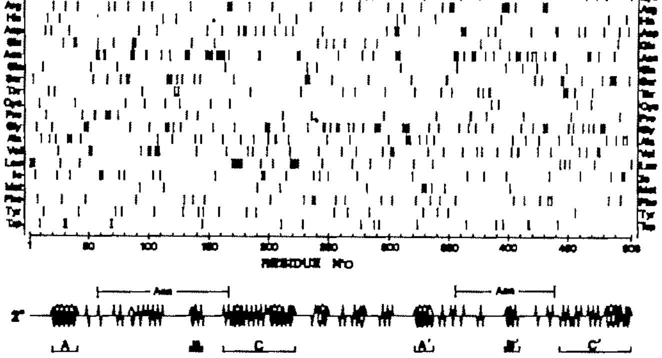

Fig. 3 The amino acid distribution and predicted secondary structure of amylase. Vertical bars indicate the sequence position of each amino-acid residue. Regions of α-helix (-▇-) and β-sheet (┼┼╫╫) were predicted using the methods of Garnier et al.[42] and Chou and Fasman[43]. The former method also predicts β-turns and random coil; however for clarity these have not been included.

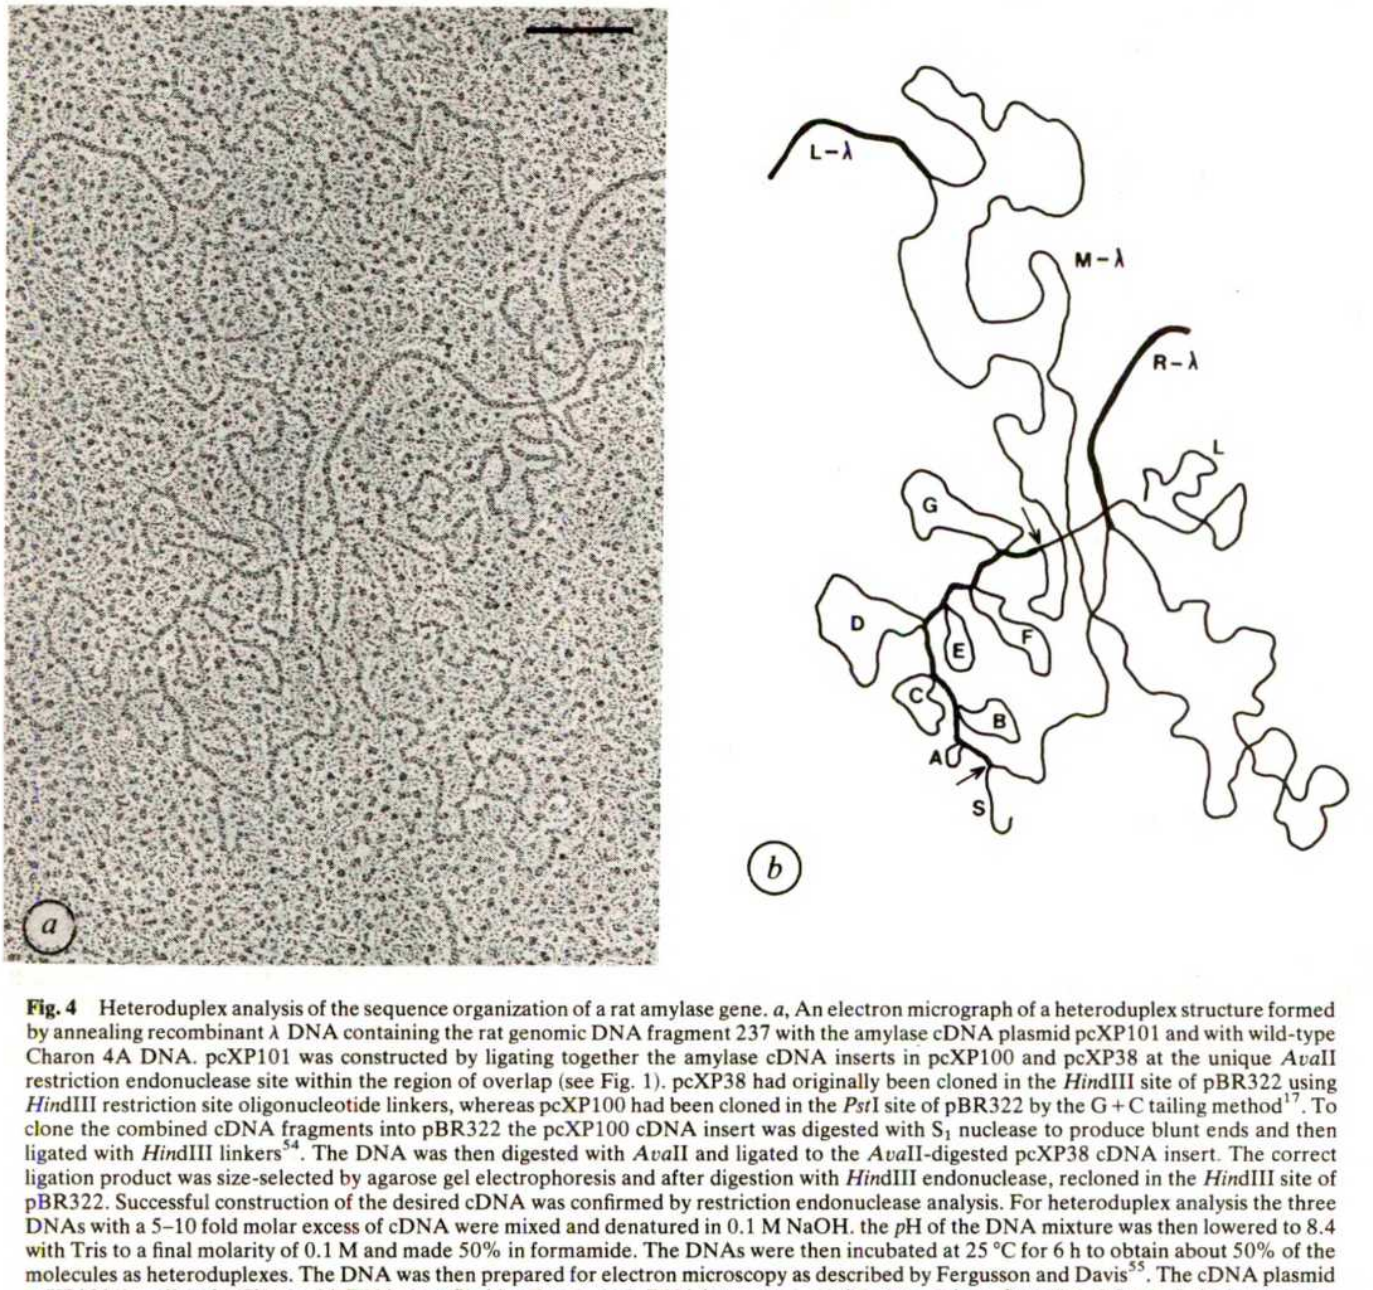

Fig. 4 Heteroduplex analysis of the sequence organization of a rat amylase gene. *a*, An electron micrograph of a heteroduplex structure formed by annealing recombinant λ DNA containing the rat genomic DNA fragment 237 with the amylase cDNA plasmid pcXP101 and with wild-type Charon 4A DNA. pcXP101 was constructed by ligating together the amylase cDNA inserts in pcXP100 and pcXP38 at the unique *Ava*II restriction endonuclease site within the region of overlap (see Fig. 1). pcXP38 had originally been cloned in the *Hin*dIII site of pBR322 using *Hin*dIII restriction site oligonucleotide linkers, whereas pcXP100 had been cloned in the *Pst*I site of pBR322 by the G + C tailing method[17]. To clone the combined cDNA fragments into pBR322 the pcXP100 cDNA insert was digested with S_1 nuclease to produce blunt ends and then ligated with *Hin*dIII linkers[54]. The DNA was then digested with *Ava*II and ligated to the *Ava*II-digested pcXP38 cDNA insert. The correct ligation product was size-selected by agarose gel electrophoresis and after digestion with *Hin*dIII endonuclease, recloned in the *Hin*dIII site of pBR322. Successful construction of the desired cDNA was confirmed by restriction endonuclease analysis. For heteroduplex analysis the three DNAs with a 5–10 fold molar excess of cDNA were mixed and denatured in 0.1 M NaOH. the *p*H of the DNA mixture was then lowered to 8.4 with Tris to a final molarity of 0.1 M and made 50% in formamide. The DNAs were then incubated at 25 °C for 6 h to obtain about 50% of the molecules as heteroduplexes. The DNA was then prepared for electron microscopy as described by Fergusson and Davis[55]. The cDNA plasmid pcXP101 as well as the Charon 4A DNA arms flanking the genomic DNA insert were used as size markers. Scale bar, 0.2 μm. *b*, An interpretive drawing of the heteroduplex structure in *a*. Intervening sequences are designated A–G in the direction of transcription of the gene. Arrows delimit the region of homology between the genomic fragment and the cDNA. Single-stranded DNA tails present at the ends of the gene sequences marked S and L represent the short and long tails of pBR322, respectively. The double-stranded DNAs situated at the ends of the heteroduplex structures marked L-λ and R-λ represent the left and right arms of Charon 4A DNA, respectively, and M-λ represents the middle region of the wild-type Charon 4A DNA.

which exhibit undiminished enzyme activity and nearly identical tryptic peptide maps. Hydrodynamic and low angle X-ray scattering measurements[38] as well as preliminary X-ray crystallographic data[39,40] indicate a molecule consisting of two similar but non-identical lobes separated by a cleft. Although in need of confirmation by X-ray crystallography, significant structural homology between the halves of the proposed amino acid sequence (divided between residues 270 and 271) is suggested by comparison of the halves of the sequence according to the method of McLachlan[41] and by the secondary structure predicted from the proposed sequence according to the methods of Garnier *et al.*[42] and Chou and Fasman (ref. 43 and Fig. 3). Predicted regions of α-helix and β-sheet designated A, B and C (Fig. 3) in the amino-terminal half of the sequence are repeated as similar but non-identical regions A′, B′ and C′ in the carboxyl-terminal half. Asparagine-rich clusters are present in each half and are located symmetrically between regions A and C and A′ and C′. A Pro-Pro sequence is present in each half of the sequence (positions 54–55 and 367–368) located similarly with respect to regions A and A′. A glycine-rich region (21% glycine residues extending from position 245 to 316) separates the two putative domains. The sequence Arg-Lys is present at positions 274 and 275 in the approximate middle of the molecule, and may correspond to the protease-hypersensitive site observed by Robyt *et al.*[36].

A comparison of the two putative domains reveals no significant sequence homology between these regions at either the amino acid or nucleotide level. Conservation of intramolecular structural homology despite retention of little or no amino acid sequence homology has been observed in penicillopepsin[44] and rhodanese[45]. In view of the lack of nucleotide sequence homology between the putative domains the origin of the two domain structure, which could be via fusion of tandemly duplicated primordial genes[46], remains an open question.

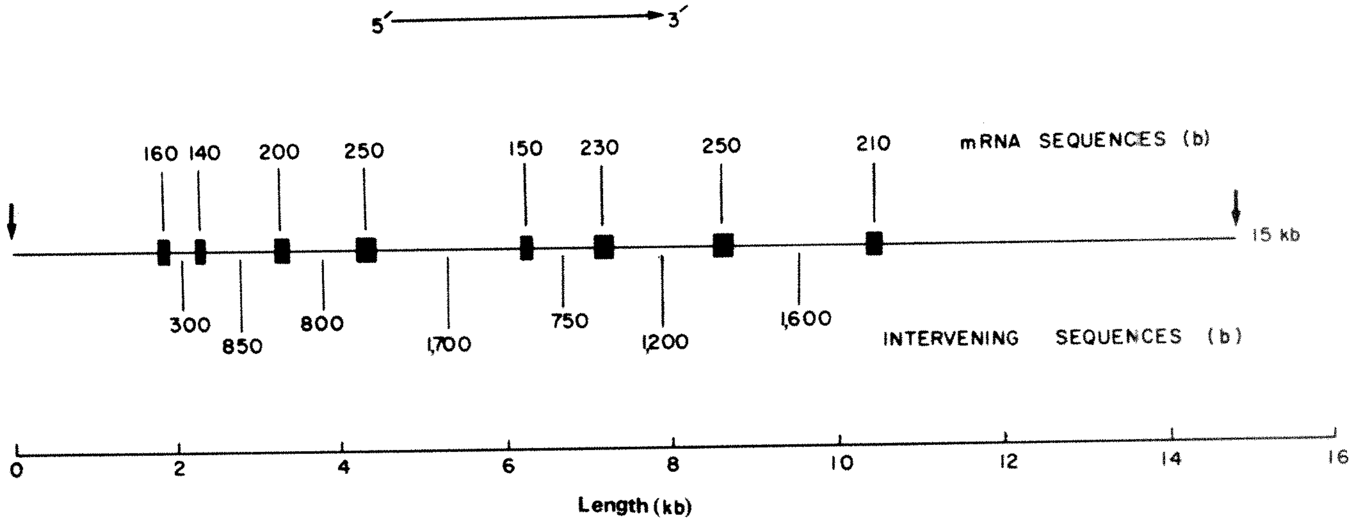

Fig. 5 A schematic representation of the organization of amylase gene sequences in the genomic DNA fragment 237. The lengths of the mRNA (cDNA) and intervening sequences are mean values derived from measurements of at least four heteroduplex structures. Standard deviations range from ±5% for the larger to ±20% for the smallest measurements. λ Charon 4A DNA sequences are not shown here and the arrows indicate the ends of the genomic fragment. kb, kilobases.

Amylase gene structure

Using the cDNA inserts of pcXP100 and pcXP38 as probes, we have screened a rat genomic DNA-lambda Charon 4A DNA library (provided by T. Sargent, R. B. Wallace and J. Bonner[47]) for phage containing rat amylase gene sequences by the method of Benton and Davis[48]. Thirty-nine positive recombinant phage were obtained from 2×10^6 plaques and were subsequently purified and analysed.

The organization of amylase gene sequences within these fragments was determined by restriction endonuclease analysis and electron microscopic examination of heteroduplexes formed by annealing the DNA of the recombinant phage with the amylase cDNA plasmid designated pcXP101. This plasmid was constructed by joining the cDNA inserts in pcXP100 and pcXP38 at a common, unique restriction endonuclease site as detailed in the legend to Fig. 4. The combined cDNA was recloned in pBR322 and its 5′ to 3′ orientation within the plasmid was determined by restriction endonuclease analysis. On digestion of pcXP101 with *Sal*I, a linear molecule with a short strand of pBR322 sequences (0.6 kilobase pairs) at the 5′ end and a long strand (3.7 kilobase pairs) at the 3′ end of the cDNA insert is formed. Amylase genomic sequences could then be orientated after hybridization to this probe by measuring the pBR322 tails present at the ends of the genomic DNA·cDNA hybrid. Wild-type Charon 4A DNA was also included in the heteroduplex mixture to delimit the left and right λ arms which flank the genomic DNA fragments. Genomic sequences flanking the amylase gene sequences could then be identified.

The 39 positive fragments obtained from the library appear to represent nine distinct amylase genes. However, the overall sequence organization as determined by heteroduplex analysis suggests that these genes are all related to a common amylase gene motif. Figure 4*a* and *b* show, respectively, an electron micrograph and the corresponding interpretative drawing of a heteroduplex structure of a gene which exhibits the structural features found in the other gene fragments. This genomic fragment contains cDNA sequences that are interrupted by seven detectable intervening sequences; 5′ and 3′ flanking regions are also present. Estimates of the lengths of these regions are given in Fig. 5. Amylase cDNA sequences are present within a region of 9 kilobases and range in length from approximately 140 to 250 bases. The correspondence of the aggregate lengths of these sequences (1,600 ± 100 bases) with the length of the cDNA probe (1,547 bases), suggests that the entire length of the cDNA is hybridized to the genomic fragment in the heteroduplex. The lengths of the intervening sequences range from approximately 300 to 1,700 bases. Flanking regions extend 2 and 4 kilobases from the 5′ and 3′ ends, respectively, of the amylase gene sequence. We emphasize that the present experiments do not detect sequences at the extreme 5′ end of the mRNA since these sequences are missing in the cDNA probe; intervening sequences have been observed in this region in a number of eukaryotic genes[20,49–53]. Since the 5′ flanking region is 2 kilobases long it is likely that sequences corresponding to the 5′ end of the mRNA are present in this genomic fragment. More extensive 5′ flanking regions, up to 12 kilobases long, are present in other genomic fragments. A sequence analysis of this region should prove useful in analysing tissue-specific gene expression.

Since the library used for this analysis was constructed from a single rat[47], the nine cloned amylase sequences must represent at least five non-allelic genes or pseudogenes. In fact, the nine sequences can be arranged into four closely related pairs by the patterns of restriction endonuclease digestion. With this isolation and characterization of the cDNA and genes it is now possible to envisage a more penetrating analysis of their selective expression in various differentiated cells.

We thank William Nikovits for helping with the electron microscopy, Drs Robert Fletterick and David Agard for help in analysing the proposed amino acid sequence of amylase, Dr G. H. Swift for critical discussions and help with DNA sequencing, Dr H Martinez for computer programs for DNA sequence analysis, Drs T. Sargent, R. B. Wallace and J. Bonner for supplying the recominant DNA library of rat nuclear DNA, Dr G. Marchis-Mouren for sending us the partial amino acid sequence of pig pancreatic amylase, and Dr H. Boyer and F. Blattner for providing the cloning vectors pBR322 and λ Charon 4A, respectively. This research was funded by NIH grant AM21344.

Origin of the 5 March 1979 γ-ray transient: a vibrating neutron star

An unusual γ-ray transient was observed on 5 March 1979, with 12 different instruments on 9 different spacecraft[1–4]. Most of these instruments are incorporated into an interplanetary γ-ray burst network. The source position of the 5 March transient, determined by this network to an accuracy[4] of $\sim 1\times 2$ arc min, is consistent with the direction of the supernova remnant N49 in the Large Magellanic Cloud (LMC). Subsequent analysis[5] of the data, by narrowing the source error box to an area of about 6 by 30 arc s inside the supernova remnant, considerably strengthens this identification. We propose that a vibrating neutron star in the LMC is the source of the 5 March transient. This may be both the first detection of a vibrating neutron star and indirect evidence for gravitation radiation.

In addition to its identification, the 5 March transient has several unique characteristics that set it apart[3,6] from the general class of γ-ray bursts: the peak flux of $\sim 10^{-3}$ erg cm^{-2} s^{-1} in the impulsive phase of the event is an order of magnitude greater than that of any other γ-ray burst. At the distance of the LMC (55 kpc), this implies a luminosity of $\sim 3\times 10^{44}$ erg s^{-1}. The duration of the impulsive phase, $\sim$0.15 s, is also shorter than that of most γ-ray bursts which last for several seconds. The 5 March impulsive energy release, $\sim 5\times 10^{43}$ erg, would thus be larger by more than five orders of magnitude than typical γ-ray burst energies, whose probable galactic origin[7] requires energy releases of only $\sim 10^{38}$ erg.

The exceedingly short rise time of this impulsive phase, $<2\times 10^{-4}$ s, suggests that the size of the emission region does not exceed $\sim$60 km, the light travel distance for this time. That the source may in fact be a neutron star is implied by the energy spectrum[1] of the impulsive phase (Fig. 1) which shows a broad feature centred at $\sim$0.4–0.43 MeV probably due to the gravitational redshift of 0.511 MeV electron–positron annihilation radiation. This radiation should be produced close to the surface of a neutron star with $z=(1-2GM/Rc^2)^{-1/2}-1\cong 0.19$ to 0.28 where M and R are the mass and radius of the star. Similar redshifts have been reported for at least one other γ-ray burst[8,9] and longer duration γ-ray transients[10,11].

A neutron star origin for the 5 March event is also suggested by the observed[1–3] pulsations which follow the impulsive phase for at least 3 min. The pulse period is 8.0 ± 0.05 s, and the average pulsed flux, $\sim 10^{-5}$ erg cm^{-2} s^{-1}, decreases exponentially with a characteristic time of $\sim$50 s. These pulsations could be due to rotation, although the period seems to be too long for a young ($\lesssim 10^4$ yr) neutron star in N49. Such pulsations have not been seen from any other γ-ray burst. The 5 March transient was also followed by three other outbursts[9], apparently from the same source direction, on 6 March, 4 April and 24 April. The peak intensities of these outbursts, however, were much lower than that of the 5 March event, and decreased with each burst.

The energy spectrum of the 5 March event is much softer than that of typical[12] γ-ray bursts. In fact, the bulk of the emission of the 5 March event is in the lower energy ($\lesssim 0.2$ MeV) part of the spectrum which is significantly steeper than that of other γ-ray bursts[13,14] in this energy range.

Although the burst source position strongly suggests association with N49, there are several problems if the source were a neutron star in the LMC. These concern the origin and rapid release of the observed energy, and the very high efficiency of the radiation mechanism. The required mechanism apparently violates the black-body limit in that it must provide a very large luminosity at relatively low photon energies from a small emitting area. Indeed, several authors, using arguments based on the Eddington limit for accretion models[1], on the opacity of γ rays to Compton scattering and pair production[15,16], and on the slow diffusion of photons to the neutron star surface[17], have concluded that the source of the 5 March transient should be closer than a few hundred parsec.

Here we consider that the source of the 5 March transient is in the LMC, based on the rather convincing positional identification with N49. The arguments against an LMC origin based on radiation mechanisms are removed by the e^+–e^- synchrotron cooling and annihilation model presented elsewhere[18] and briefly discussed here. Regarding the energy source, its very large magnitude requires that it be interior to the star, most likely of gravitational origin. The transport of this energy cannot be by photon diffusion. We propose instead that

neutron star vibrations could, in a coherent and rapid fashion, communicate the internal energy to the upper crust and atmosphere. Decay of these vibrations by gravitational radiation[19] would then account for the duration of the impulsive phase, ~0.15 s. An LMC origin for the 5 March transient is not in conflict[6,20] with a galactic origin for the more common γ-ray bursts, as these probably belong to a different class of transients than does the 5 March event.

The basic source of energy in the 5 March transient is not clear, but it could be gravitational energy released by a phase transition[21] in the interior. In this case, the energy should be communicated to the surface in a time comparable to the sound-wave crossing time through the neutron star. As the speed of sound in neutron star matter is[22] of the order c, this time is less than the upper limit in the rise time of the burst. The released gravitational energy could be much larger than observed in γ rays, but the bulk of this energy is not expected to be emitted as electromagnetic radiation. A large fraction of the released energy could in fact be in vibrations[22], $E_{\text{vib}} \cong 10^{53}$ erg $(\delta R/R)^2$, where δR is the vibrational amplitude. For example, if $\delta R/R \sim 10^{-3}$, $E_{\text{vib}} \sim 10^{47}$ erg, in which case conversion of only a small fraction (10^{-3}) of this energy into γ rays would be sufficient to account for the observations.

The strong magnetic fields that are tied to the neutron star play an important part in this conversion. As these fields oscillate together with the surface, they should produce wave motions which would accelerate particles in the atmosphere. In particular, the bulk motions may be converted into magnetoacoustic waves, the high frequency portions of which dissipate in the atmosphere and heat it. Because of the relatively small number of ambient atmospheric particles, this heating would rapidly raise the temperature to a value ($\lesssim 10^9$K) at which e^+-e^- pair production sets in. Further heating increases the radiation density, and the atmosphere becomes radiation dominated. In this case, the density of pairs which coexist with the radiation greatly exceeds that of the ambient matter. As this hot pair plasma attempts to escape from the neutron star, it pushes the magnetic field outwards. But the field, being tied to the star, is compressed, and in the resulting strong field regions the pairs are rapidly cooled by synchrotron radiation.

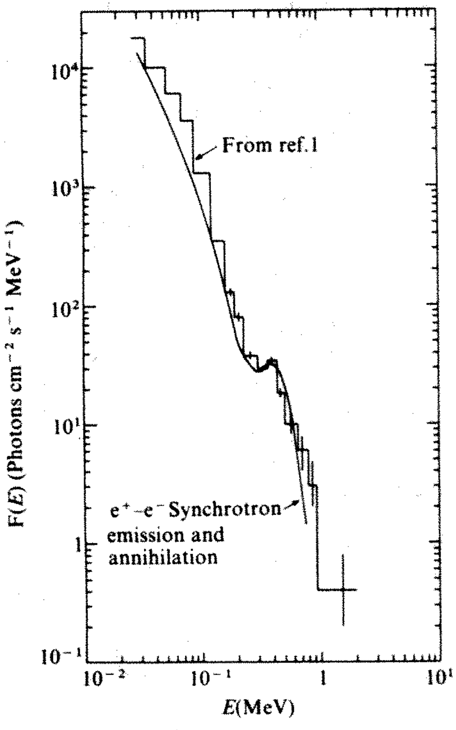

Fig. 1 Energy spectrum of the impulsive phase of the 5 March transient measured[1] during the first 4 s of the event. The photon flux of the impulsive phase is larger than that shown in the figure by a factor of 4/0.15, where 0.15 s is the duration of the impulsive phase. The curve is the calculated[18] spectrum in the e^+-e^- synchrotron cooling and annihilation model.

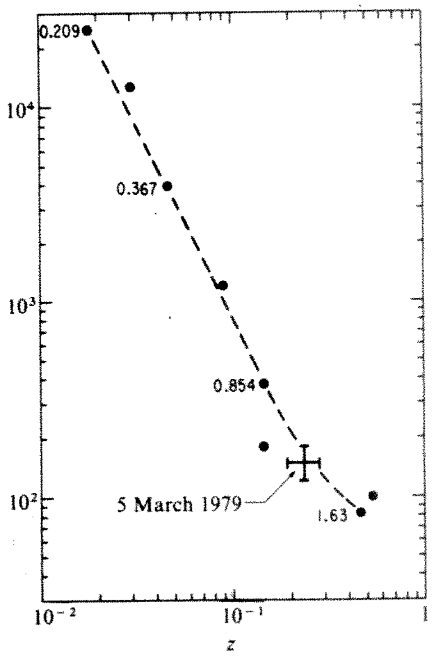

Fig. 2 The calculated[26] (●) quadrupole gravitational radiation damping time versus gravitational redshift for neutron stars. The dashed curve connects cases having the same equation of state and the numerical values are neutron star masses in units of $M_\odot$. The datum point is from γ-ray observations of the 5 March transient[1-3].

The e^+-e^- synchrotron cooling and annihilation model[18], which we now briefly describe, can account (see Fig. 1) for the observed impulsive spectrum. The essential feature of this model is the radiation dominated e^+-e^- pair plasma. Even though its annihilation time is very short ($\sim 10^{-12}$s for the parameters[18] of the 5 March transient), this plasma can maintain itself because the annihilation photons have enough energy to produce new pairs. The energy spectrum of the coexisting radiation, however, is much harder than the observed spectrum. But in regions of strong magnetic field, the pairs can lose their kinetic energies before they annihilate and this converts the hot (~MeV) photon-pair plasma into cooler radiation (~tens of keV) that is devoid of pairs. This conversion takes place in a layer whose thickness does not exceed the photon–photon pair production mean free path. This outer skin layer is also the effective radiating volume of the star. The magnetic field, the pair density and the thickness of the layer are $\gtrsim 10^{11}$ G, $\sim 2 \times 10^{26}$cm^{-3}, and 0.1 mm, respectively[18]. The curve in Fig. 1 is the calculated[18] spectrum produced in the layer: the low energy part ($\gtrsim 0.2$ MeV) is the synchrotron radiation of the pairs, while the high energy part is their annihilation radiation.

The stability and confinement of the radiating layer is an essential requirement of the model, because its absence would lead to relativistic outward expansion that would result in blueshifted radiation rather than the redshifted emission needed to account for the observations. We believe that the magnetic field does play a major role in the confinement, as the energy density in the field is at least as large as that of the e^+-e^- plasma. In particular, confinement may be achieved in the highly compressed magnetic field ahead of the pair plasma. The positive (outward) gradient of the field should exert an inward confining force on the plasma. Possible instabilities, such as the exchange instability, and a radiation-pressure driven Rayleigh–Taylor instability, may be stabilized by the continuous transformation of particles into photons and vice versa, as well as by the strongly sheared field.

The conversion of the neutron star vibrational energy into γ rays should go on as long as the star continues to vibrate. The principal damping mechanism of the vibrations should be gravitational radiation[19]. Neutrino emission[23] is an important damping mechanism only for very young hot neutron stars, while viscous effects (the Urca process and a process[24] involving Σ^- hyperons) are slower[22] than gravitational radiation damping. Escaping shock waves can also damp the vibrations[22], but the loss rate due to shocks should not exceed the observed electromagnetic emission which in our model constitutes only a small fraction of the vibrational energy.

Gravitational radiation is expected to damp the quadrupole and higher mode vibrations on time scales ranging from about 0.1 to 10 s, depending on the properties of the neutron star[25,26]. Using the calculations of Detweiler[26], we plot in Fig. 2 the damping time τ as a function of redshift z, where the dashed curve connects points obtained from the same equation of state. The numerical values next to these points are the corresponding neutron star masses in units of $M_\odot$. The 5 March 1979 datum point shows the observed[1–3] duration of the impulsive phase (120–180 ms) versus the approximate redshift[1]. The implied neutron star mass is ~1–1.3 $M_\odot$, its radius ~10 km, and its quadrupole vibrational frequency ~0.4 ms. The sensitivities of the present gravitational wave detectors were insufficient to observe the expected gravitational radiation (J. A. Tyson, personal communication), and the time resolution of the γ-ray instruments were insufficient to resolve the expected vibrational period in the impulsive emission.

Although gravitational radiation is very effective in damping the quadrupole and higher mode vibrations, it will damp the radial oscillations more slowly[19,22]. The Σ^- process[24], however, could damp the radial vibrations on a time scale of ~50 s, the characteristic decay time of the pulsed phase of the 5 March transient. Thus, the energy source for this phase as well could be neutron star vibrations. The observations would, therefore, imply that the γ-ray luminosity produced by the radial oscillations is smaller than that of the higher modes. This could result from asymmetric excitation of the vibrations which would put more energy into nonradial vibrations. Also, due to its small scale height, the atmsphere is expected to couple better with the higher modes than with radial oscillations. The 8-s period of the pulsed emission, however, is not likely to be a vibrational period. It may be caused by the rotation of the neutron star, although neutron star precession is an alternative explanation (K. Brecher, personal communication). The subsequent weaker bursts, which seem to come from the same source on 6 March, 4 and 24 April, may be aftershocks of the 5 March burst if it indeed results from a major quake in the neutron star interior.

There are, of course, several unresolved aspects of the model that clearly need further study. These include the more precise description of the source of energy of the burst, the nature and efficiency of vibrational heating, the stability of the thin emission region, and the origin of the 8-s pulsed emission. The present general outline of a model for the 5 March transient can account for both the enormous luminosity and the complex temporal and spectral features of the burst by emission form a neutron star in the LMC.

Low energy γ rays from PSR1822−09

P. Mandrou & G. Vedrenne

Centre d'Etude Spatiale des Rayonnements–CNRS–UPS BP 4346,
31029 Toulouse Cedex, France

J. L. Masnou

CEA, CEN–SEP Saclay BP 2, 91190 Gif sur Yvette, France

Pulsed γ-ray emission in the MeV range (80 keV–6 MeV) has been clearly established[1–4] for the Crab pulsar PSR0531+21 ($P = 33$ ms). The energy spectrum of the pulsed component follows a power law from the X-ray (100 keV) to the high energy γ-ray range (2. GeV) with an index close to 2.1 (ref. 5). Positive detection of pulsed γ ray emission from the Vela pulsar PSR0833−45 ($P = 89$ ms) has been claimed in the 10–30 MeV region by Albats *et al.*[6], and clearly established[6] in the high energy range 50 MeV–3 GeV with a power law index of 1.9. This pulsar was also observed in the X-ray range but with apparently conflicting results (ref. 7 and refs therein), some authors reporting positive detection while other have upper limits below the reported values. Other radio pulsars, especially PSR1822−09, and PSR1747−46 have been investigated at energies above ~50 MeV by the satellites SAS 2[8,9] and COS B[10]. We report here observations of PSR1822−09 ($P = 769$ ms) between 80 keV and 6 MeV at balloon altitudes.

The equipment used, which is described in detail elsewhere[11], consisted of a 10-cm diameter CsI(Tl) crystal (78.5-cm^2 area), 2.5-cm thick, shielded against background by an active NaI(Tl) well 5-cm thick and 8-cm high blocked off at the bottom by 2 NaI(Tl) disks, a total of 10-cm thick whose diameters were the same as the outside diameter of the well (20 cm). The detector field of view, defined by the anticoincidence well, is a cone of half angle 45°. A plastic scintillator 0.5-cm thick was placed against the CsI(Tl) detector to block out charged particles entering the aperture. In the absence of an anticoincidence signal, the CsI(Tl) pulses were analysed by two 128 channel ADCs[12] covering the energy ranges of 80–1,126 keV and 1.5–6 MeV. All events detected during the flight were dated with a ground based clock to within 0.1 ms. The stability of the datation process was checked using a simultaneous recording of a 10^5 Hz oscillator. Gain variations, checked in flight by the observation of the atmospheric 511-keV line, are <1%.

The response of the detector in both energy and angle with respect to the viewing axis was determined in the laboratory using 14 calibrated radioactive sources whose energies covered the range 80 keV–8 MeV. This calibration gives a response matrix for the detector which is used to find the incident photon spectrum using the detected electron spectrum[13].

The telescope, mounted vertically, was launched from Guaratinguetà, Brazil (latitude 22°48′ S, rigidity 11.7 GV) on 12 February 1977. During this flight, which lasted 5 h at a ceiling altitude of 2.4 g cm^{-2}, the galactic disk was observed[14]. As the pulsar PSR1822−09 was also in the field of view, the data were analysed to see whether the pulsar signature could be detected.

We have divided the data into three energy intervals. The pulsar light curve in each energy range, was constructed by folding the data, consisting of all the events, modulo the

0028–0836/80/370124—03$01 00

apparent period, into 10 phase bins, each event being placed in one of the bins as a function of its arrival time. The apparent period was found from the radio values of P and $\dot{P}$ given by Taylor and Manchester[15] after extrapolation to the date of the flight (JD = 2443187.0), and correction for the Doppler effect due to the movement of the Earth; the source was taken to be at the right ascension given by Manchester *et al.*[16] and the declination given by Taylor and Manchester[15]. Only the data taken between zenith angles 13° and 33° were used, which correspond to times between 10:45 and 14:00 UT; the effective exposure at 1 MeV was 3.9×10^5 cm^2 s^{-1}.

Figure 1 shows the light curve obtained between 454 and 1,126 keV. The χ^2 value for this distribution is 16 for 9 d.f., corresponding to a probability $P(\chi^2 \geq 16)$ of 0.07. A Monte Carlo simulation was used to evaluate the overall probability resulting from the three phase histograms obtained using the energy ranges: 80–454 keV ($P = 0.4$); 454–1,126 keV ($P = 0.07$); and 1.5–6 MeV ($P = 0.15$). An overall probability of <1% was obtained. The light curve in the energy range 454–1,126 keV has two characteristic peaks separated by a phase of 0.5 ± 0.1. This structure is also found for PSR0531+21 and for PSR0833–45, above a γ-ray energy of 50 MeV. From this comparison, the two peaks labelled A and B in Fig. 1 have been chosen as pulsed bins in the light curve. The background level is defined using the six remaining bins. With respect to this level, the number of pulsed events (in A and B) is at a 3.4 standard deviation above this background level. Peak A is ~230 ms wide; peak B is 77 ms wide. The intensity ratio between peaks A and B is ~3.

The energy spectrum of the pulsed events was constructed by distributing equally all the data (80 keV–6 MeV) into four energy channels. The incident photon spectrum, corrected for atmospheric absorption, is shown in Fig. 2. A positive detection is observed only for the two channels: 300–530 keV ($(3.1 \pm 1.2)10^{-3}$ photons cm^{-2} s^{-1} MeV^{-1}) and 530–1,126 keV ($(3.8 \pm 1.2)^{-3}$ photons cm^{-2} s^{-1} MeV^{-1}). The pulsar was not detected either between 80 and 300 keV (3 σ upper limit 4.4×10^{-3} photons cm^{-2} s^{-1} MeV^{-1}) or between 1.5 and 6 MeV (3 σ upper limit 6.7×10^{-4} photons cm^{-2} s^{-1} MeV^{-1}). Figure 2 also shows 3 σ upper limits for these two channels, as well as the upper limit between 30 and 80 MeV tacking the upper limit of the flux above 35 MeV (2.7×10^{-6} photons cm^{-2} s^{-1}), from SAS 2[8], and assuming an $E^{-2.4}$ spectrum.

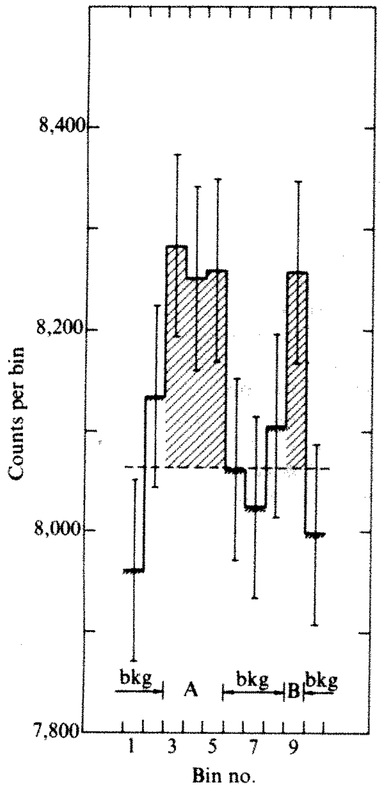

Fig. 1 Light curve observed for PSR1822 – 09 in the energy range 454–1,126 keV. $P(\chi^2 \geq 16/9 \text{ d.f.}) = 0.07$. The dashed line represents the background level.

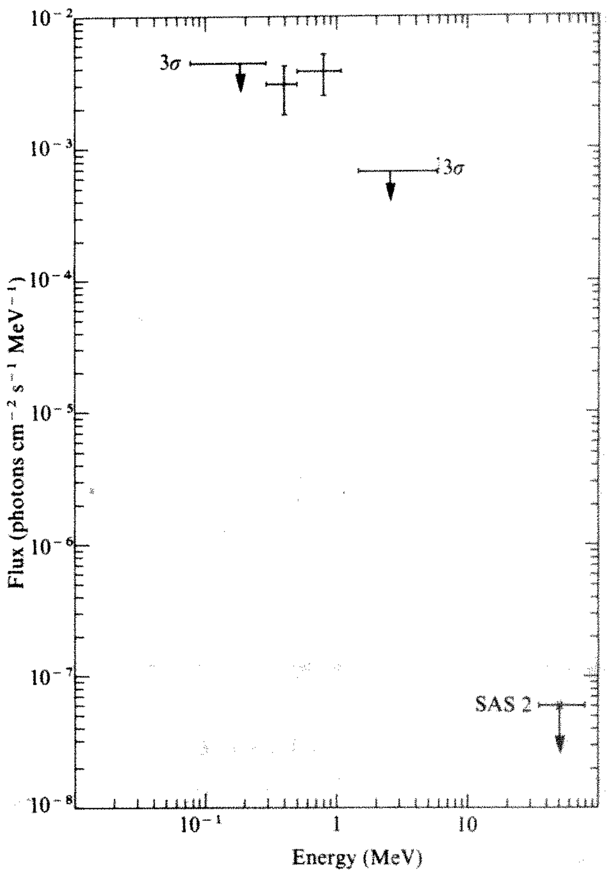

Fig. 2 Energy spectrum for PSR1822 – 09 using the pulsed events in the two peaks (see text).

This spectrum is very different from that observed in the case of the Crab pulsar which is a power law equal to –2.1. It shows a remarkable break around 1 MeV, the index being smaller than –2 above this energy taking into account the SAS 2 upper limit, and close to zero below 1 MeV, if we consider the upper limit between 80 and 300 keV.

Various theories have been invoked to explain pulsar emission. Some of them consider that this emission is localized near the crust of the neutron star[17,18] and others, at the light cylinder[19,20]. In the first model, the high energy particles are accelerated near the crust of the neutron star and propagate along the open magnetic field lines. These particles produce high energy photons by curvature radiation. The primary γ photons can be absorbed by pair production when they cross the magnetic field lines. The secondary particles created by this process emit instantaneously a flux of γ-ray photons by the synchrotron process. The resulting spectral shape depends on the pulsar period, the Lorentz factor of the primary electrons (positrons) and the intensity of the magnetic field at the neutron star pole. Above 1 MeV, the observed spectral index is then consistent with a Lorentz factor for the primary particles of $\simeq 10^7$ or less.

Around 1 MeV our data show a clear break in the spectrum: this could be due to a synchrotron self-absorption process or to a pair-production absorption process. Our results imply that the most important part of the energy emitted by PSR1822 – 09 is emitted in the MeV region. Other observations in this energy range are necessary to confirm this result and to understand better the geometry of the γ emission for this pulsar.

We thank Professors J. Heyvaerts and L. Scarsi for helpful discussions. This work was supported by CNES contract BA 011 02 F.

Discussion of the Pioneer 11 observations of the F ring of Saturn

W.-H. Ip

Max-Planck-Institut für Aeronomie,
D-3411 Katlenburg-Lindau 3, FRG

The photopolarimetric and charged particle data from the Pioneer 11 Saturn encounter were used as diagnostic tools in a preliminary analysis of the physical nature of the F ring of Saturn. It is argued that the F ring may have two components, with the outer one composed of solid particles of centimetre-diameter and the inner one of micrometre-sized dust particles. Also, the outer component as scanned by the charged particle detectors may have two rings instead of one. The double-ring option, if verified, could have interesting implications for the dynamical origin of the planetary ring systems.

Among the many exciting new results from the recent Pioneer 11 flyby of Saturn[1,2] one of the major findings is the discovery of a new (F) ring located at 2.33 R_s (Saturn radius) just outside the A ring by the Imaging Photopolarimeter (IPP) team[3]. The absorption effects of trapped charged particles by this ring were subsequently detected by the particle experiments[4–7]. According to the IPP observations, the F ring has a width of no more than 800 km and an optical depth of $\leqslant 2\times10^{-3}$. In comparison with the whole saturnian ring system the F ring is very narrow indeed. Interestingly, there may be structures of even smaller scale in the F ring. First, the IPP team found indication of clumpiness in the ring. Second, the charged particle absorption features (the electron data, in particular) displayed distinct variations between 2.34 R_s and 2.36 R_s (refs 4, 5). These structures, if reflecting the condensation of matter around the F ring, would mean the presence of one or more rings (or satellites) with dimensions between 100 and 200 km.

Clearly, the particulate distributions are basic to the understanding of the F ring structure and the charged particle absorption taking place there. While some considerations on the nature of the F ring have been given by the Pioneer 11 experimenters[4,5,7], and by Dermott *et al.*[8]) in connection with their theoretical study of the narrow rings of Jupiter and Uranus, a more detailed ring model will be constructed here taking advantage of the published IPP and charged particle results. As planetary ring absorption is likely to play an important part in the budget of trapped radiation in the magnetospheres of Jupiter and Uranus as well as that of Saturn, we take the F ring as an example to outline some of the essential points of interaction between the planetary rings and the magnetospheric plasma. In particular we will explore the possibility of deducing the physical nature of the planetary rings from a combination of the optical and charged particle observations.

The most interesting F ring absorption features concern the sharp minima at 2.340 and 2.355 R_s observed in both of the inbound and outbound passes together with a central dip in the electron flux of 10 MeV energy range, which was detected only in the inbound pass[4,5]. Briefly, such absorption structures could be produced by three different (idealized) combinations of the ring system:

(1) One single circular ring in a dipole field with certain equatorial offset ($\Delta r \approx 0.01\ R_s$);
(2) One single elliptical ring in a dipole field with negligible equatorial offset ($\Delta r \ll 0.01\ R_s$);
(3) Two circular rings in a dipole field, again, with negligible equatorial offset.

The first two cases are essentially similar and the actual situation may be intermediate between them (that is, one single elliptical ring in a dipole field slightly offset with $\Delta r \leqslant 0.01\ R_s$, see Dermott *et al.*[8]) and this class of ring models will be illustrated by considering case (2). As shown in Fig. 1, charged particles drifting at different L shells would traverse different lengths of the ring material and hence experience varying degrees of reduction in particle flux[9]. As a result of such a longitudinal sampling effect, a radial profile of the absorption feature would be quite non-uniform with absorption minima formed at the inner and outer edges of the sweeping corridor of the ring. If we assume that the absorption profiles (such as locations and widths of the absorption dips) should have a certain correspondence with the radial variation of the integrated mass density or effective optical thickness, some physical parameters of the F ring may be derived. For instance, a plausible choice in which case the ring particles are bound by two orbits with $a_1 = 2.3500\ R_s$, $a_2 = 2.3479\ R_s$, $e_1 = 0.00468$, $e_2 = 0.00415$, and that the lines of apsides of these two orbits are aligned, could give a reasonable fit to the Chicago data[4]. Note that the maximum width of the F ring is about 200 km and the minimum only 50 km here, while the absorption effect extends over a region of 1,400 km. Such a ring configuration resembles the ϵ ring of Uranus[10–13], and by the same token this narrow ring is most likely maintained by a small satellite[8]. Whilst the double absorption minima flanking the ring are caused by the effect of longitudinal sampling of the charged particles, a sharp drop in the particle flux due to local absorption would also be observed if the spacecraft is situated in the near vicinity of the satellite or the main body of the ring (as may be the case for the inbound pass).

Some estimate for the optical thickness of the absorbing particles may be obtained by examining the two absorption minima. As outlined before[7,14–16], the cumulative reduction effect as the charged particles diffuse inward across a radial distance ΔL can be expressed by the survival probability given as:

$$P = \exp(-2N_b\tau) \tag{1}$$

Where N_b is the total number of bounces executed by the charged particles and τ the effective optical depth of the absorbing particles with diameter larger than the absorption range R (~ 5 cm). Defining the radial diffusion time scale as:

$$t_d = \frac{(\Delta L)^2}{4D} \tag{2}$$

(D is the radial diffusion coefficient), and the bounce period t_b is taken to be 2.4 s as appropriate for the 10 MeV electrons. Then with the relation $N_b = t_d/t_b$ plus using $\Delta L \approx 200$ km we find

$\tau \leqslant 3.4 \times 10^6 D$ as $P \approx 5 \times 10^{-2}$ at the outer absorption minimum observed in the outbound pass[4]. Since no more than 20% of the ring material will be sampled in one drift the actual relation should read: $\tau \leqslant 0.8 \times 10^7 D$.

Only upper limits of D have been given [$D < 10^{-8}\ R_s^2\ s^{-1}$ at $3.1\ R_s$, or $D < 6 \times 10^{-7}\ R_s^2\ s^{-1}$ at $3.1\ R_s$ and $10^{-7}\ R_s^2\ s^{-1}$ at $2.5\ R_s$ (ref. 7)]. Consider that the radial diffusion coefficient in the saturnian magnetosphere might have a very steep L-dependence as in the case of the Earth's magnetosphere ($D \propto L^{10}$, see ref. 17), it is possible that $D \leqslant 10^{-9}\ R_s^2\ s^{-1}$ at the position of the F ring; thus $\tau \leqslant 0.8 \times 10^{-2}$. This value is compatible with the value of $> 5 \times 10^{-5}$ as derived from using a somewhat different method[7], and with the IPP result of $\leqslant 0.8 \times 10^{-2}$ if the width of the ring is taken to be 200 km.

Although these values appear to be in satisfactory agreement, the diffusion time scale (t_d) as determined by equation (2) is probably too short in comparison with the drift period of the 7–17 MeV electrons in question (that is, 3×10^3 s compared with 7×10^4 s). In other words, two narrow rings with complete coverage at all longitudes [that is case (3)] might be required instead of just one with partial longitudinal coverage which allows rapid refilling of the absorption dips. To this binary ring system we should add another satellite orbiting between them with semimajor axis $a \approx 2.35\ R_s$ and eccentricity $e \approx 0.004$.

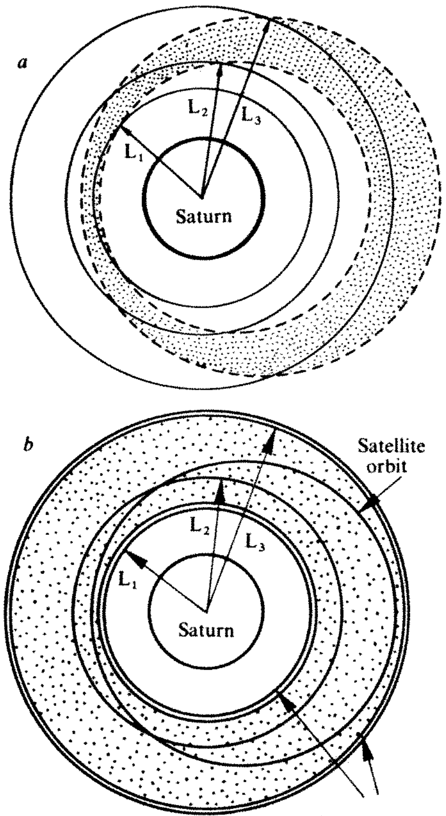

Fig. 1 Sketch of two possible ring configurations to interpret the observed charged particle absorption effects. *a*, One single ring with certain eccentricity and varying width. The charged particles drifting in different L shells would penetrate through different mass of ring material resulting in the formation of sharp absorption minima near perihelion and aphelion. If the diffusion time scale across the ring width is too short the absorption dips due to such longitudinal sampling effect could be refilled at certain positions. *b*, Two circular rings flanking the orbit of a small satellite in elliptical orbit. Two absorption minima would always be imprinted at all longitudes in the charged particle fluxes. If the spacecraft passes directly above or below the ring or satellite, an absorption spike would be observed as well as the inner and outer dips. Also the dipole offset, assumed to be zero here, could actually have a value like a fraction of $0.1\ R_s$.

The physical basis for the formation of such a system may be depicted as follows. After the fragments are ejected from the satellite surface at low speeds as a result of meteoritic bombardment or tidal stress, they would first follow trajectories approximating that of the parent satellite. However, they will be gradually cleared away within the sweeping corridor of the satellite, because of recapture by the satellite, or inward and outward diffusion due to inelastic collision with the satellite or with other small particles. The process of orbital dispersion, in any case, cannot continue forever as it is limited by the collisional frequency and mass density distribution of the interacting medium. It can be easily seen then there will be material piled up at the regions just bordering with the perihelion and aphelion of the satellite. As the particles injected into these edges would all have near circular orbits as a result of prior inelastic collisions, no further orbital dispersion could occur[18]; in this way two narrow rings of dense matter would be formed confining a wider zone of more diffuse nature. Note that such an orbital equilibrium configuration has been discussed before by Hénon[19] but in a somewhat different context.

A clear choice of the F ring configuration is difficult, but the possibility of a binary ring system is emphasized here as it has the potential of shedding new light on the structures of the rings of Uranus and Jupiter.

Another apparent puzzle in the Pioneer data may have some implication on the structure of the F ring—there is no signature of absorption of charged particles at the central position ($2.33\ R_s$) of the F ring as identified by the IPP team. Barring systematic error in the spacecraft position by a margin of 0.01–$0.02\ R_s$ for this moment, we would have to conclude that the F ring detected by the imaging experiment was not responsible for the charged particle absorption. This has several interesting implications about the F ring system.

First, in order to reduce its absorption power but amplify its cross section for light reflection the optical component of the F ring must consist mainly of tiny dust particles of submillimetre size if not smaller. To check this point let us note that the survival probability for charged particles diffusing across a belt of dust particles with average diameter $d \ll R$ can be written as:

$$P = \exp(-2N_b X/R) \qquad (3)$$

where $X = 2d\tau/3$. Now, with $P \gtrsim 0.95$ as judged from the electron data[4,5,7] we have immediately $d \leqslant 5.2 \times 10^{-3}$ cm if the ring width ΔL is about 800 km and $d \leqslant 2.1 \times 10^{-2}$cm if $\Delta L \approx 200$ km. In the above calculation we have assumed $D \approx 10^{-9}\ R_s^2\ s^{-1}$ and $\tau \approx 2 \times 10^{-3}(800/\Delta L)$. If the albedo α of these particles is smaller than unity d would be even smaller. In the extreme case of $\alpha \approx 0.05$, as was found for the uranian ring particles[20,21], we have $d \leqslant 3 \times 10^{-4}$–$10^{-3}$cm. From this point of view, the F ring identified by the IPP experiment may be in fact a dust belt of micrometre-sized particles similar to the jovian ring[22,23].

Second, to boost the absorption power but limit the cross section for light reflection to a small value the ring particles between $2.34\ R_s$ and $2.36\ R_s$ must be of centimetre size if not larger. Also, to explain the absence of this ring in the optical observation a low albedo must be invoked. In this way an optical thickness of $\leqslant 3 \times 10^{-3}$ (for $\alpha \approx 0(1)$) as required to interpret the absorption feature would be reduced to be $\leqslant 2 \times 10^{-4}$ if $\alpha \approx 0.05$. Such a value of optical depth may be below the limit of optical detection. On dynamical grounds, particles of metre size or so are required to maintain the stability of the narrow ring configuration against Poynting-Robertson effect[24]. But is there reason for such a low albedo? Presumably so, as whatever volatile ices on the particle surface would be sputtered away by the energetic ions exposing the (carbonaceous chondritic?) core material of low albedo[25]. [A similar thing can be said of the particles at the outer edge of the A ring in which case there is a difference of about $0.02\ R_s$ between the IPP result and the charged particle data[3–7].]

Finally, that the dust belt of micrometre-sized particles should be located inside of the narrow ring of larger particles is consistent with its being of fragmentation origin—as proposed for the jovian ring[26–29]. Note that the rings of both Jupiter and Uranus have been suggested to be the fragments of small satellites which are spiralling inwards towards the central planets. According to Dermott *et al.*[30], for instance, the reason for such orbital decay is basically that the synchronous orbits of both Jupiter and Uranus are outside the Roche limits, so satellites formed between these two positions would be pulled inward as a result of planetary tidal action. For Saturn, the synchronous orbit at 1.8 R_s is inside of the Roche limit at 2.3 R_s, so a reverse process might take place there—with small satellites accreted from condensations in the A ring being gradually pushed away from the planet. The F ring and its parent satellite are then manifestations of just such a process[26].

We have discussed here the possibility that the F ring may have two components: (1) the inner one mainly consisting of micrometre-sized dust particles (detected by the IPP experiment), and (2) the outer one of centimetre- to metre-sized bodies emitted from a small satellite (observed by the charged particle detectors). This scenario makes interesting comparison with the discovery of the ring system of Jupiter[22,23,31,32]. We have also investigated the possibility of deducing the ring configuration capitalizing on the radial profiles of the observed absorption features of the charged particles. Besides the more conventional configuration of one single narrow ring we find that a double-ring system is also a possibility—if not strictly required by the particle data. Detailed intercomparison of the Pioneer IPP, particles and fields observations may allow us to narrow down some of the uncertainties. Also, the Voyager I flyby in November, which follows essentially the same trajectory, should provide another set of valuable data. From analysis of charged particle experimental data, Simpson *et al.*[33] have concluded that the symmetric pair of the F ring absorption dips observed both inbound and outbound, is caused by two separate narrow rings; Gehrels[34] has found that the high colour index of the optical F ring is consistent with the idea that it is made of micrometre-sized dust particles.

I thank Drs W. I. Axford, W. Fillius and C. K. Goertz for useful discussions on the single ring option, and Drs J. A. Simpson and T. Gehrels for sending me preprints prior to publication.

Order-modulated structures and the thermodynamics of cordierite reactions

A. Putnis

Department of Earth Sciences, University of Cambridge,
Downing Street, Cambridge CB2 3EQ, UK

The determination of palaeo pressures and temperatures (*P, T*) in metamorphic belts is of fundamental importance to our understanding of large-scale physical processes in the Earth. Such determinations are made by comparing observed mineral assemblages with experimental data on their *P, T* stability fields[1], thus assuming that the experiments are an adequate model for the natural reaction. The characterization of the structural state of natural and experimental materials is particularly important in this context. This note demonstrates the effect of the state of cation order on the *P, T* slopes of metamorphic reactions involving cordierite, $(Mg, Fe)_2Al_4Si_5O_{18}$, an indicator phase in metamorphism. Particular emphasis will be placed on the mechanism of Al, Si ordering in cordierite in so far as it relates to the characterization of the degree of cation order and hence the configurational entropy contribution to the thermodynamics of cordierite reactions.

Mg-cordierite occurs in two polymorphic forms. In the high temperature hexagonal structure, stable above ~1,450 °C (refs 2, 3), the Al and Si atoms are distributed over two sets of tetrahedral sites—three T_1 and six T_2 sites per formula unit $Mg_2Al_4Si_5O_{18}$ (Fig. 1). The Al, Si distribution involves two Al and one Si atom disordered over the T_1 sites and two Al and four Si atoms disordered over the T_2 sites[4]. In the slightly distorted low temperature orthorhombic form the T_1 sites are split into two non-equivalent sites T_11 and T_16, while the T_2 sites are split into a set of three non-equivalent sites T_21, T_26 and T_23. Within this new structure the Al, Si atoms are able to form a completely ordered distribution (see Table 1).

Experiments carried out on the mechanism and kinetics of the hexagonal–orthorhombic transition in anhydrous Mg-cordierite confirm that the polymorphism is due to Al, Si ordering and furthermore demonstrate that in equilibrium conditions the ordering transformation is first order involving the discontinuous transformation from a disordered to a well ordered phase at temperatures below ~1,450 °C (refs 3, 5).

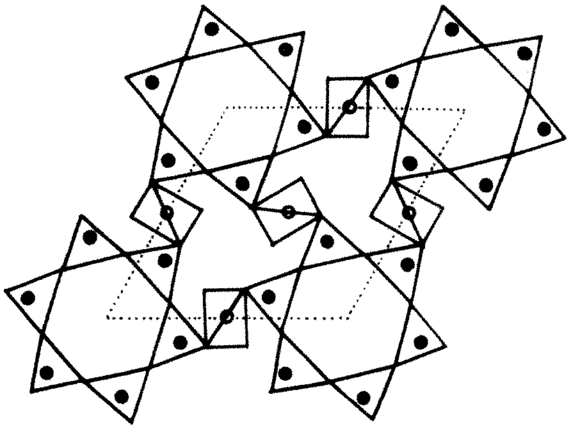

Fig. 1 The structure of hexagonal cordierite showing only the tetrahedral linkages. The tetrahedra in the ring sites (●) are designated T_2, while those outside the ring (○) are designated T_1 in Table 1. The dotted line is the hexagonal unit cell.

0028–0836/80/370128—04$01.00

This polymorphism has been generally characterized by a distortion index Δ, based on the degree of splitting of the peaks derived from the 211 hexagonal peak in an X-ray diffractometer trace[6]. In the hexagonal form Δ is zero, while in the fully ordered orthorhombic form of anhydrous Mg cordierite $\Delta \approx 0.25°$. In nature, however, cordierites of intermediate Δ values are common[7] and although various compositional effects have been proposed to account for this[8-10], the occurrence of these intermediate states in anhydrous Mg-cordierite[2] has yet to be explained. The strongly first order nature of the transformation precludes the formation, in equilibrium conditions, of intermediate structural states. As intermediate cordierites are formed from hexagonal cordierite at temperatures substantially below the equilibrium ordering temperature (that is, in the stability field of fully ordered cordierite), it is pertinent to examine the mechanism of Al, Si ordering in non-equilibrium conditions.

Isothermal annealing experiments were carried out on stoichiometric Mg-cordierite glass at temperatures between 1,150 and 1,430 °C for periods of 0.5–400 h. The preparation and characterization of the starting material and experimental details are given elsewhere[3]. The products of the annealing runs were studied by X-ray diffractometry and transmission electron microscopy.

The first phase to crystallize from the glass is invariably homogeneous hexagonal cordierite, which eventually transforms on annealing to homogeneous orthorhombic cordierite, the stable phase. The mechanism of the transformation in metastable conditions, however, does not involve the direct nucleation and growth of the orthorhombic phase. The transformation proceeds by the formation of a modulated structure in which two orthogonal distortion waves produce a 'tweed' microstructure in transmission electron micrographs (Fig. 2). The average structure as observed by X-ray diffractometry is hexagonal, whereas locally the structure consists of a sinusoidal variation in the degree of distortion towards two twin-related orthorhombic variants. The overall structure may be described as order-modulated, in which the short-range order may be high, while the long-range order, as measured by X-ray diffraction, is zero.

Continued annealing results in a gradual overall coarsening of the microstructure although the unequal development of one or other variant may lead to regions in which the distortions become unbalanced. This manifests itself as a slight departure from the average hexagonal state, and an apparently continuous range of Δ values is obtained by the increasing heterogeneity and growth of the microstructure. The first signs of peak splitting in the X-ray diffractometer traces must already be equated with a considerable degree of coarsening of the microstructure, on a scale of thousands of angstroms. Full details of the coarsening mechanisms will be published elsewhere, but there are two principal conclusions which can be drawn from these results. First, a mechanism which involves the formation of a metastable order-modulated structure will not be detected by methods such as X-ray powder diffractometry which measure long-range effects, and hence any assessment of the structural state obtained by such methods may be in error. Second, the mechanism described here is quite different in character from the temperature-dependent ordering models used by workers currently dealing with the thermodynamics of cordierite reactions[11-13].

Table 1 Tetrahedral sites in the cordierite polymorphs

Nine sites per formula unit $Mg_2Al_4Si_5O_{18}$

Hexagonal form	Orthorhombic form	Site content
3 T_1 sites	2 T_11 sites	2 Al
	1 T_16 site	1 Si
6 T_2 sites	2 T_21 sites	2 Si
	2 T_23 sites	2 Si
	2 T_26 sites	2 Al

Table 2 Volumes and entropies of minerals at 700 °C and 1 atm (ref. 12)

	Volume (cm^3 gfw)	Entropy (cal °C gfw)
Cordierite $2MgO.2Al_2O_3.5SiO_2$ gfw = 584.97	234.01	264.58
Sapphirine $2MgO.2Al_2O_3.SiO_2$ gfw = 344.63	100.55	151.38
Quartz SiO_2 gfw = 60.085	23.72	27.34

One major assumption in the experimental determination of the *P*, *T* stability field of anhydrous cordierite has been that the configurational entropy contribution of Al, Si order is not large[12,13]. This assumption is based on several lines of evidence all of which depend on an interpretation of the limited data provided by X-ray powder diffraction. First, measured heats of solution of Mg-cordierite with Δ values of 0.10, 0.20 and 0.25 prepared in metastable conditions are not significantly different[11,12]. As Al, Si disorder is normally accompanied by considerable enthalpy effects, the conclusion is that all of the samples were similar and had a high degree of order. While this conclusion is in itself valid, it is interpreted in terms of a model in which the degree of order is assumed to be related to a continuously changing Δ value with temperature. Hence the observation that a considerable change in Δ value corresponds to a small inferred change in cation distribution is extrapolated to suggest that hexagonal cordierite with a Δ value of zero must have a high degree of Al, Si order.

However, the order-modulated mechanism described here suggests a different interpretation of the same observations. Ordering via an order-modulated structure results in a high degree of short-range order without any change in symmetry. Thus calorimetric measurements of order-modulated material would be expected to produce results very similar to that of fully ordered orthorhombic cordierite, and subsequent increases in Δ on annealing would have little further enthalpy effects. However, the essentially discontinuous nature of the ordering processes on a local level in the transition from homogeneous hexagonal cordierite (that is disordered) to order-modulated hexagonal cordierite does not allow extrapolation of intermediate Δ values to zero.

Conventional single crystal X-ray structure analysis is not able to distinguish between a completely disordered hexagonal cordierite (Table 1) and the order-modulated state described here, and although the Bragg–Williams order parameter seems to be the same in each case[4], the configurational entropy of the two states may be radically different, as discussed below.

The extent to which the configurational entropy contribution to the total entropy change in a metamorphic reaction affects the *P*, *T* slope may be calculated from the Clapeyron relation $dP/dT = \Delta S/\Delta V$. Although the volumetric effects of cation disorder are negligible, the configurational entropy may be the dominant term, particularly in solid–solid reactions where the overall entropy changes are small. This is well illustrated by the reaction:

$$\text{Anhydrous cordierite} \rightarrow \text{sapphirine} + \text{quartz}$$

$$2MgO.2Al_2O_3.5SiO_2 \rightarrow 2MgO.2Al_2O_3.SiO_2 + 4SiO_2$$

Table 2 shows the volume and third law entropy data from which dP/dT may be calculated. To evaluate the effect of configurational entropy of cordierite alone, the configurational entropy of sapphirine will be taken to be fixed at +4.2 cal per °C gfw as suggested by Newton *et al.*[12]. The validity of this assumption will be discussed below.

The entropy change for the reaction involving fully ordered cordierite ($S_{\text{config.}} = 0$) is therefore given by tabulated third law entropies:

$$\begin{aligned}\Delta S_{\text{reaction}} &= S_{\text{sapph}} + 4S_{\text{qtz}} - S_{\text{cord}} \\ &= (151.38 + 4.2) + (4 \times 27.34) - 264.58 \\ &= 0.32 \text{ cal per °C gfw} \\ \Delta V_{\text{reaction}} &= -38.3 \text{ cm}^3 = -0.915 \text{ cal bar gfw}\end{aligned}$$

Therefore

$$\frac{dP}{dT} = -0.35 \text{ bar per °C}$$

To calculate the slope for this reaction when the cordierite is completely disordered, the configurational entropy of the cordierite must be evaluated. Taking four Al and five Si atoms disordered over the nine T_1, T_2 sites taken together,

$$\begin{aligned}S_{\text{config.}} &= -9R\left(\frac{4}{9}\ln\frac{4}{9} + \frac{5}{9}\ln\frac{5}{9}\right) \\ &= 12.0 \text{ cal per °C gfw}\end{aligned}$$

For the hexagonal structure described in Table 1 with two Al and one Si atoms disordered over T_1 sites and two Al and four Si atoms disordered over T_2 sites

$$\begin{aligned}S_{\text{config.}} &= -3R\left(\tfrac{2}{3}\ln\tfrac{2}{3} + \tfrac{1}{3}\ln\tfrac{1}{3}\right) - 6R\left(\tfrac{2}{6}\ln\tfrac{2}{6} + \tfrac{4}{6}\ln\tfrac{4}{6}\right) \\ &= 11.34 \text{ cal per °C gfw}\end{aligned}$$

Thus, although the Bragg–Williams order parameter of this state[4] may suggest that it is partially ordered, its configurational entropy is very high. In contrast, an order-modulated state with the same apparent long-range order parameter would have a very small configurational entropy.

The dP/dT for the reaction involving hexagonal disordered cordierite with the cation distribution shown in Table 1 is

$$\frac{dP}{dT} = \frac{0.32 - 11.34}{-0.915} = 12 \text{ bar per °C}$$

The P, T slopes for the breakdown of ordered and disordered cordierite to sapphirine + quartz are shown in Fig. 3. The lines necessarily intersect at the order–disorder transition temperature (1,450 °C). The position of this intersection on the pressure axis is defined by reversed experiments and calorimetric data[12,14] in which the equilibrium for the reaction using well ordered cordierite ($S_{\text{config.}}$ assumed to be 1.22 cal per °C gfw) was found to occur in the range 8.2 ± 0.4 kbar at 1,300–1,400 °C with a slope of about 1 bar per °C. This reaction line (dotted in Fig. 3) must also pass through the order–disorder transition temperature for Mg-cordierite.

Thus, while Newton's calorimetric and experimental data are internally self consistent, they represent only one solution for a cordierite with a particular state of order. The fact that the cation disorder in cordierite cannot be dismissed as insignificant stresses the importance of carrying out thermochemical measurements, and experimental high P, high T reactions, on materials in which the state of order has been characterized. Routine transmission electron microscopy combined with X-ray diffraction of such materials can provide considerably more information on short-range order as well as on the mechanism of the ordering process. This latter point is particularly important in relation to the estimation of the relevant configurational entropy corrections.

In the above treatment the effect of disorder in cordierite has been evaluated by assuming a fixed entropy for sapphirine. However, the situation with regard to assumptions of cation order in sapphirine poses even greater problems than in cordierite. The occurrence of two polymorphs and their intimate intergrowths[15,16], and the possibility of a relationship between the polymorphism and Al, Mg and/or Al, Si disorder suggests the need for considerable caution over estimates of configurational entropy. Further, calorimetric measurements on synthetic and natural sapphirines[17] disclose differences which have been attributed to different structural states; hence the synthetic material is not a good model for its natural counterpart. The sensitivity of P, T slopes of dry reactions to configurational entropy corrections, coupled with the structural variations present in natural sapphirines, further underlines the inadequacy of assumptions of $S_{\text{config.}}$ made on the basis of a single X-ray structure analysis of a sample.

Finally, it remains to consider the relevance of a discussion of disordered phases in experimental reactions to natural assemblages. The crystallization of a disordered phase within the stability field of the ordered polymorph is frequently observed where the starting material is in a highly metastable state, such as a glass. This may be a readily understood in terms of the large overall free energy change in the reactions involved with the formation of either phase, in which case the discrimination in favour of the metastable disordered phase is on kinetic grounds, its crystallization having a higher entropy of activation.

In a metamorphic rock, conditions are generally nearer to equilibrium. Consider the prograde formation of a phase with ordered and disordered polymorphs at a temperature below its order–disorder temperature. At constant pressure, the equilibrium temperature (T_1) for any reaction producing the ordered phase will necessarily be lower than the metastable equilibrium temperature (T_2) for the same reaction producing the disordered phase. Above T_2 the enhanced kinetics would favour the nucleation of the disordered phase. Thus, the formation of disordered phases in prograde reactions requires a measure of overstepping of the stable equilibrium temperature, a nearly universal phenomenon in dry rocks.

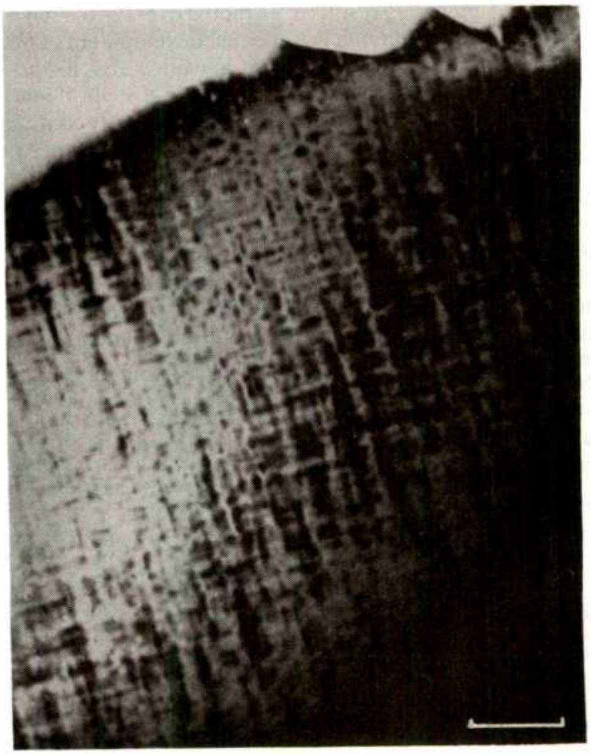

Fig. 2 Transmission electron micrograph of the order-modulated microstructure of cordierite, showing two orthogonal distortion waves normal to (100) and (1$\bar{2}$0) planes of the hexagonal cell. Scale bar, 0.2 μm.

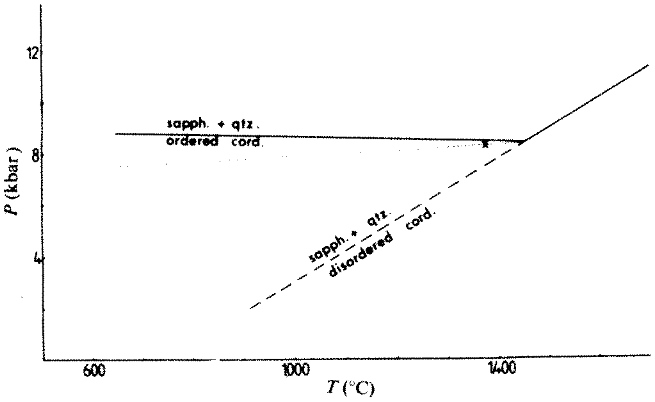

Fig. 3 Pressure–temperature equilibria for the reaction cordierite → sapphirine + quartz for ordered and disordered cordierite. The dotted line and the point X represent the slope and experimental point, respectively, determined for this reaction by Newton *et al.*[12] using a cordierite with assumed $S_{\text{config.}}$ of 1.22 cal °C gfw.

The extent to which disorder plays a major role in the growth of a mineral during metamorphism must be assessed for each individual occurrence. Furthermore, the structural state of a mineral exposed at the Earth's surface is not necessarily the same as that during its growth, and depends on the relative kinetics of the mineral reaction and the ordering process. In this respect the relict microstructure may indicate whether an ordered phase was nucleated directly or has been produced from a disordered phase subsequent to growth. The formation of intermediate structural states in cordierite strongly suggests that ordering occurs via an order-modulated structure.

The microstructures of natural cordierites have not yet been studied. However, in an investigation of the distortion indices of 128 natural cordierites[7], the whole range of Δ values from 0 to >0.25 has been found, and these show characteristic frequency distributions for various geological environments. Notwithstanding the possible compositional effects on Δ values[8–10], this supports Schreyer's hypothesis that the observed Δ values indicate an evolution from an initially disordered high cordierite[7] similar to the process in the experiments described here.

Clearly many of these implications to the *P*, *T* slopes of natural metamorphic reactions remain to be tested. The evidence suggests the need for calorimetric measurements on phases with well characterized microstructures, for repeating experiments on metamorphic reactions using both ordered and disordered reactants, and finally for the characterization of the structural states of the natural assemblages to which experimental studies are applied.

I thank T. J. B. Holland, J. D. C. McConnell and G. D. Price for discussions. Financial support from the NERC is gratefully acknowledged.

D.c. electrical conductivity of Green River oil shales

K. Rajeshwar, M. Das & J. DuBow

Department of Electrical Engineering, Colorado State University,
Fort Collins, Colorado 80523

The recent interest in the kinetics and mechanistic aspects of the thermal decomposition of oil shale kerogen[1] derives largely from its importance as an alternative energy source to petroleum. In spite of considerable research effort, how oil shale kerogen decomposes to gaseous and liquid hydrocarbon fuels is still not fully understood[1]. The present study considers the d.c. electrical conduction behaviour of Green River oil shales. The observed trends in the electrical behaviour of these materials are correlated with a two-step decomposition model in which the rate-determining processes are shown to be (1) breakdown of an outershell polar bridge structure with an activation energy of 15 ± 2 kcal mol^{-1} (180–350 °C) and (2) cleavage of an inner core naphthenic structure also involving polar groups with an activation energy of 35 ± 3 kcal mol^{-1} (350–500 °C). These structural changes are shown to correspond to the chemical transformation of kerogen to liquid and gaseous hydrocarbons through a bitumen intermediate. Although the present data pertain to Green River oil shales in particular, the observed trend of charge transfer mechanisms in the thermal decomposition behaviour of thermally unstable materials may be indicative of how thermal and electrical properties of all solid materials in general are closely coupled. The common mechanistic origin identified in the present study for the processes of thermal decomposition and electrical conduction, offers the possibility of improving the thermal stability characteristics of a solid by appropriate changes in the electric field surrounding it.

Electrical conductivity (σ) measurements were carried out in the temperature range 25–500 °C, on right circular cylindrical disks of oil shales of diameter ~2.4 cm and thickness of 0.25 cm. The direction of the electric field was perpendicular to the shale stratigraphic planes in all the cases reported below. A nominal field strength of 110 V cm^{-1} was applied across the shale sample and the currents were measured using a conventional operational amplifier circuit. Silver electrodes were used for the measurements; the opposite faces of the sample disks were also coated with silver paint to minimize contact resistance. In a typical 'run', the sample was heated in an atmosphere of dry pre-purified N_2 at a heating rate of ~2 °C min^{-1}. The required d.c. voltage was then imposed across the shale sample. Because of polarization effects, the currents slowly decayed with time at a given temperature—the values finally attaining a steady-state. This steady-state conductivity σ_∞ was recorded at various temperatures and the data displayed in the form of conventional $\ln \sigma_\infty$ versus $1/T$ plots[2].

Figure 1 shows the variation of d.c. conductivity with temperature for a Utah shale, a Colorado oil shale sample and a Wyoming shale[3]. The organic content of these samples was estimated from specific gravity measurements[4] and is expressed in terms of an equivalent Fischer assay as the volume of oil in litres that can be extracted per unit mass (tonne) of the shale. The σT versus $1/T$ plots can be broken up into approximately three segments with activation energies (slopes) E_1, E_2, and E_3 respectively. These values for the different samples and the corresponding temperature intervals are shown in Table 1. The E values within each temperature interval are seen to be comparable for the different samples within the limits of experimental error. More significantly, the slopes are also seen to be relatively insensitive to the amount of organic matter in the shale (Fig. 2 and Table 1). This evidence strongly supports the

0028–0836/80/370131—03$01.00

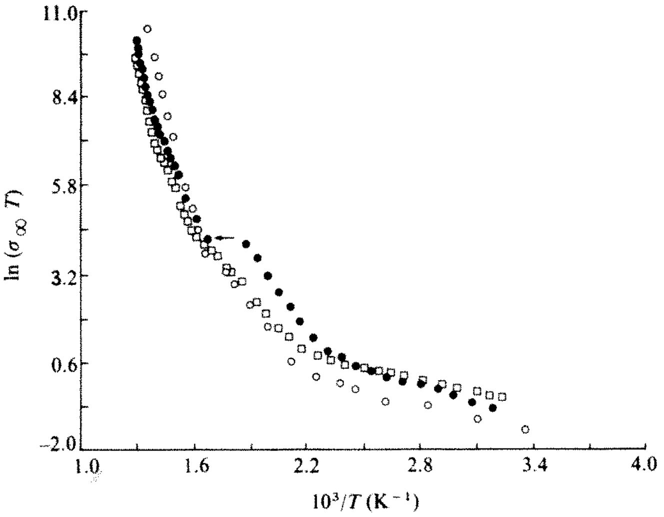

Fig. 1 Variation of steady-state conductivity with temperature for Green River oil shales: □, Wyoming oil shale (135 l tonne^{-1}); ○, Utah oil shale (344 l tonne^{-1}); ●, Colorado oil shale (140 l tonne^{-1}). The arrow denotes a set of isothermal conditions for approximately 10 min followed by resumption of the heating program (2 °C min^{-1}, see text).

linking of the observed E values to an intrinsic charge transfer process whose energetics are independent of the amount of organic matter in the shale. A dependence of the E values on the organic content of the shale would have precluded a straightforward explanation of the observed trends in terms of charge transfer processes. Chemical effects such as decomposition are expected to bring about changes in the magnitude of E with organic content in such a case. The magnitude of the measured σ values, however, do show pronounced time-dependent effects, especially at elevated temperatures (>400 °C, compare with the values denoted by arrows in Figs 1 and 2). These irreversible effects are attributed to thermal decomposition of the indigenous organic matter in the shale. Further evidence is the pronounced hysteresis in σ_∞ values that are observed after heating to ~500 °C and cooling back to room temperature. The σT versus $1/T$ plots show completely different activation behaviour in the cooling cycle. A second heating does not significantly bring about further changes and the conductivity behaviour now reflects charge migration in the residual carbon and in the inorganic mineral matrix in the shale.

Table 1 Activation energies* obtained from d.c. electrical conductivity measurements on Green River oil shales

Sample (oil yield) (l tonne^{-1})	Activation energy† (kcal mol^{-1}) (approximate temperature interval)
Utah oil shale (344)	$E_1 = 38$ (350–500 °C) $E_2 = 15$ (180–350 °C) $E_3 = 3$ (25–180 °C)
Wyoming oil shale (135) H	$E_1 = 36$ (350–500 °C) $E_2 = 14$ (180–350 °C) $E_3 = 3$ (25–180 °C)
Colorado oil shale (140)	$E_1 = 32$ (280–500 °C) $E_2 = 16$ (180–280 °C) $E_3 = 3$ (25–180 °C)
Colorado oil shale (244)	$E_1 = 34$ (350–500 °C) $E_2 = 17$ (180–350 °C) $E_3 = 2$ (25–180 °C)

* Measured values include contribution from migration enthalpies as well as carrier formation energies especially at elevated temperatures (see ref. 2).

† Nominal error in measured values, ±2 kcal mol^{-1}.

The observed trends in the electrical conductivity behaviour are consistent with a two-step decomposition process for oil shale kerogen[1]:

$$\text{Kerogen} \xrightarrow[180\text{–}350\,^\circ C]{E_1} \text{pyrobitumen}$$

$$\xrightarrow[350\text{–}500\,^\circ C]{E_2} \text{oil} + \text{gas} + \text{char} \qquad (1)$$

We propose that the two high-temperature regions in $\ln(\sigma_\infty T)$ versus $1/T$ plots (Figs 1 and 2) refer to the above reactions with activation energies E_1 and E_2 respectively, This interpretation is strongly supported by the good correlation of the present activation energies E_1 and E_2 with those measured recently in this laboratory for the thermal decomposition of Green River oil shale kerogen[5]. Using a non-isothermal thermogravimetry technique, activation energies of 14.53 kcal mol^{-1} and 36.49 kcal mol^{-1} were obtained for the low-temperature thermal decomposition of kerogen and the high-temperature decomposition of pyrobitumen respectively[5]. These values are in excellent agreement with those for E_1 and E_2 in Table 1. The close correspondence of activation energies obtained from two widely disparate techniques—one electrical and the other thermal—underlines a common origin for the processes of charge carrier migration and thermal decomposition in Green River oil shales. As only charged species contribute to the d.c. conductivity, the primary bond-breaking step must involve polar molecules in both stages of reaction (1). A previous structural model[6,7] for oil shale kerogen, involves a non-uniform three-dimensional network wherein the major components (such as isoprenoids, steroids, and terpenoids) are linked by bridges to form the kerogen matrix. Based on the present data, we propose that rupture of cross-linking bridges, most of which are polar in nature (disulphides, ethers and ester groups), is the rate-determining step in both pyrolysis as well as in charge migration. Two types of polar bridges are envisaged: (1) the first 'outershell' group which interlinks the major components and is broken first in the first stage of decomposition and (2) a second 'core' type which holds together the carbon skeletal chain (predominantly naphetenic) within each individual component and is ruptured in the second stage of pyrolysis[7]. The proposed mechanism is consistent with the increased solubility observed for kerogen at the end of the first pyrolysis step; the reduced

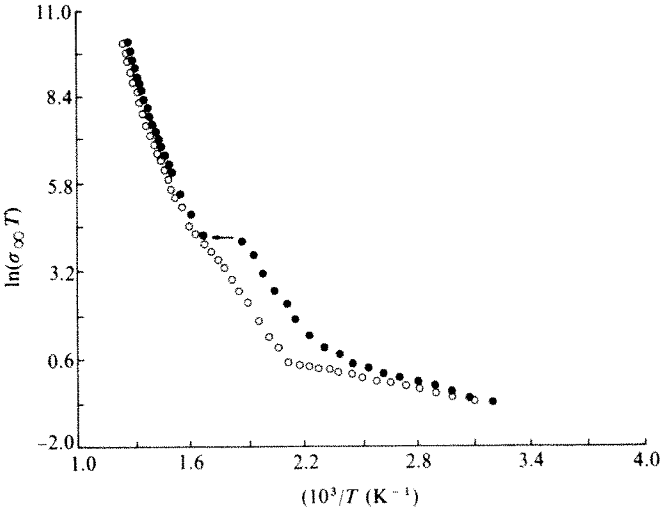

Fig. 2 Comparison of d.c. electrical conductivity behaviour for Anvil Points (Colorado) oil shales containing two different levels of organic content: ●, 140 l tonne^{-1} (same sample as in Fig. 1); ○, 240 l tonne^{-1}.

degree of cross-linking as a result of the breakdown in the bridge structure is expected to enhance the solubility of kerogen markedly.

The conductivity in the low-temperature region is expected to arise mostly from the indigenous moisture in the shale. This process is assigned an activation energy, E_3 (compare with Table 1). The water molecules are presumably trapped within the kerogen macromolecular network. The extremely low E_3 values observed at low temperatures imply a chain mechanism for conduction presumably of the Grotthus-type[8].

Finally, although the present conductivity data have highlighted the importance of charge transfer in the thermal decomposition of oil shale kerogen, further measurements are necessary to elucidate the exact nature of these charged species. Note that similar conductivity measurements on a variety of solid fuels (such as coals) could yield a unified picture of the mechanistic aspects of charge migration and thermal instability in these materials.

We thank the US Department of Energy and the Laramie Energy Technology Center for financial support.

Late-Glacial history of the Brecon Beacons, South Wales

M. J. C. Walker

Department of Geography, Saint David's University College,
Lampeter, Dyfed SA48 7ED, UK

In the uplands of the Brecon Beacons, Black Mountains, Fforest Fawr area of South Wales, small arcuate moraines and/or protalus ramparts are found below steep escarpments and in glacial cirques[1–3]. The freshness and distinctive morphology of many of these features have led to the suggestion that they are not a product of the late Devensian ice sheet, but may have been formed during the Loch Lomond Stadial of the Late-Glacial period (Fig. 1), the last occasion when glaciers existed in the British Isles. I present here pollen-stratigraphic evidence and radiocarbon dates which form the basis for the first Late-Glacial chronology for this area of South Wales, and which prove that the features described above developed during the Loch Lomond Stadial (approximately equivalent with the Younger Dryas of Scandinavia[4–6]).

Within the catchment of Glyn Tarell, on the northern side of the Brecon Beacons escarpment (Fig. 2), two distinctive end moraines occur. Beneath the north-east-facing scarp of Craig-y-Fro (grid ref. SO 972208), an arcuate ridge extends for about 0.75 km down the western slope and crosses the valley floor at ~365 m OD, while in the cirque of Craig Cerrig-gleisiad (grid ref. SO 964220), the innermost of a complex of glacial depositional landforms (some of which may be the product of the late Devensian ice sheet) is a prominent boulder-strewn, arcuate moraine at a height of ~425 m OD. Both moraines enclose infilled kettle-hole basins in which Flandrian limnic and terrestrial sediments have accumulated. The subsurface contours of the two basins were established by sounding the infills along a grid pattern[7] and the deepest points were located. In this way, the oldest sediments in the basins could be sampled. Overlapping cores were then removed with a piston corer for pollen analyses and radiocarbon dating.

Fig. 1 The Late-Glacial period.

At Traeth Mawr (grid ref. SO 967257), some 3.5 km north of Craig Cerrig-gleisiad (Fig. 2), a large dead-ice hollow at ~330 m OD contains a typical Late-Glacial sequence[8] comprising organic muds between minerogenic sediments, and these deposits are, in turn, overlain by Flandrian muds and peats. Cores were removed from a deep part of the basin for pollen analyses, and samples for radiocarbon dating were obtained by bulking material from comparable stratigraphic horizons in six of the cores. As at the sites within the moraines, this procedure was made possible by the clearly defined stratigraphy of the basin sediments. The full stratigraphic sequences at the three sites, the pollen assemblage zones and the dated horizons are shown in Fig. 3. The radiocarbon dates are presented in Table 1.

Three dates were obtained from the Late-Glacial profile at Traeth Mawr, the earliest of which, 11,660 ± 140 BP (SRR-1562), was from the basal organic sediments. The pollen spectra from those horizons show marked upward trends in the curves for *Betula* and *Juniperus*, increases in aquatic taxa and declining values for open-habitat herbs such as *Artemisia* and *Rumex*. The radiocarbon date is, however, over 1,000 yr younger than age determinations from comparable Late-Glacial Interstadial deposits in Scotland[9–12], the Lake District[13–15], North Wales[16] and Cornwall[17]. One reason for this is that initially low productivity within the lake during the early Late-Glacial Interstadial could have led to a very slow rate of sediment accumulation, and as deposition probably increased with the development of the lacustrine ecosystem, it would be extremely difficult to obtain a true age for the basal organic sediments from a 2-cm thick sample of material. This problem may have been exacerbated by the compaction of the unconsolidated organic sediments, a process that can result in several hundred years of sedimentary

Table 1 Radiocarbon dates from the Brecon Beacons

Sample no.	Site	Depth below surface (cm)	Date (yr BP)	δ^{13}C value
SRR-1560	Traeth Mawr	287–289	9970 ± 115	−16.9‰
SRR-1561	Traeth Mawr	369–371	10,620 ± 100	−17.8‰
SRR-1562	Traeth Mawr	397–399	11,660 ± 140	−16.4‰
SRR-1563	Craig-y-Fro	442–444	10,030 ± 100	−29.0‰
SRR-1564	Craig Cerrig-gleisiad	550–552	10,860 ± 70	−25.6‰

0028–0836/80/370133—03$01.00

history becoming compressed into a few centimetres[18]. A third possibility is that the date has been affected by the incorporation of younger carbon, either during the sampling process or through sediment mixing on the former lake floor. Any of these factors, either singly or in combination, could have produced the date of 11,660 ± 140 BP which, in the context of other age determinations from Highland Britain, would seem to be anomalous.

The uppermost Interstadial deposits at Traeth Mawr yielded a date of 10,620 ± 100 BP (SRR-1561). At that level in the profile there is a marked decline in percentages of woody plant pollen, particularly *Betula* and *Juniperus*, the virtual disappearance of the thermophilous herb *Filipendula* cf. *ulmaria*, and a pronounced increase in percentages of taxa indicative of open habitats, notably *Rumex*, *Artemisia* and species of Caryophyllaceae and Cyperaceae. SRR-1561 agrees closely with the date of 10,590 ± 185 BP obtained from a similar biostratigraphic horizon at a site in south-east Ireland[19] (although that assay was made on a 10-cm thick sample), but is markedly younger than the age of 11,000 BP assigned to the beginning of the Younger Dryas Chronozone in north-west Europe[4]. In Scotland and parts of northern England, the onset of cold climatic conditions and the build-up of Loch Lomond Advance ice seem to have begun before 11,000 BP (refs 5, 20), and thus the dates from Traeth Mawr and south-east Ireland, if correct, reflect the later onset of Stadial conditions and subsequent glacier development. This, in turn, might have been caused by time-transgressive southward movement of the oceanic Polar Front[21], but additional dates are required from other areas of western Britain to test this hypothesis.

The end of the Loch Lomond Stadial at Traeth Mawr is dated at 9,970 ± 115 BP (SRR-1560). These early Flandrian horizons are characterized by high Gramineae frequencies, a rising *Juniperus* curve and low arboreal percentages. The radiocarbon date agrees well with dates of 10,080 ± 320 BP, 10,060 ± 380 BP and 10,170 ± 220 BP obtained from basal Flandrian sediments in infilled pingo basins in south Cardiganshire[22–24], and a date of 10,200 ± 220 BP from the base of the Flandrian sequence in Tregaron Bog in west Wales[25], although the large standard errors on these latter dates mean that the true ages of the dated samples could be somewhat earlier. If correct, however, the radiocarbon determination from the Brecon Beacons and from adjacent regions seem to be slightly younger than the conventional age of 10,300 BP which is generally accepted as marking the close of the Late-Glacial period in Britain, and are also younger than dates which have recently been obtained for the wastage of Loch Lomond Advance ice from Rannoch Moor in western Scotland[7,26–28]. Collectively, they imply continued minerogenic inwash into lake basins (possibly associated with periglacial activity) for some time after such processes had ceased to operate in other areas of Britain. The reason for this is unclear, for it would be expected that the effects of climatic amelioration, particularly vegetational development and the trend towards soil stability, would have been experienced first in the more southern and western areas of the British Isles. Further research is clearly needed to resolve this paradox.

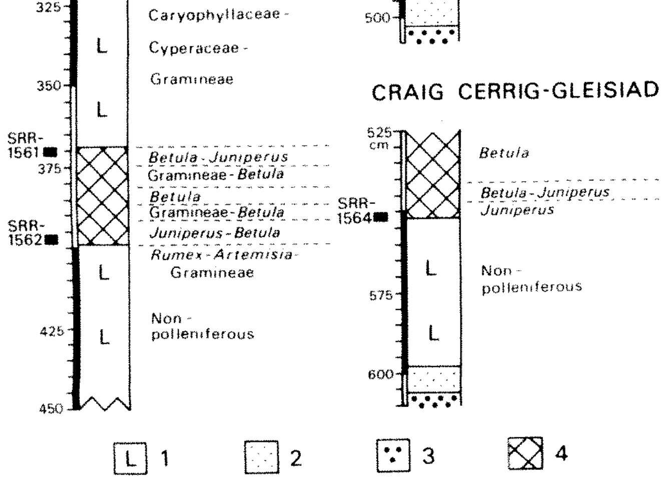

Fig. 2 The Brecon Beacons. Contour interval 100 m. The morainic areas are shown by heavy stipple-shading.

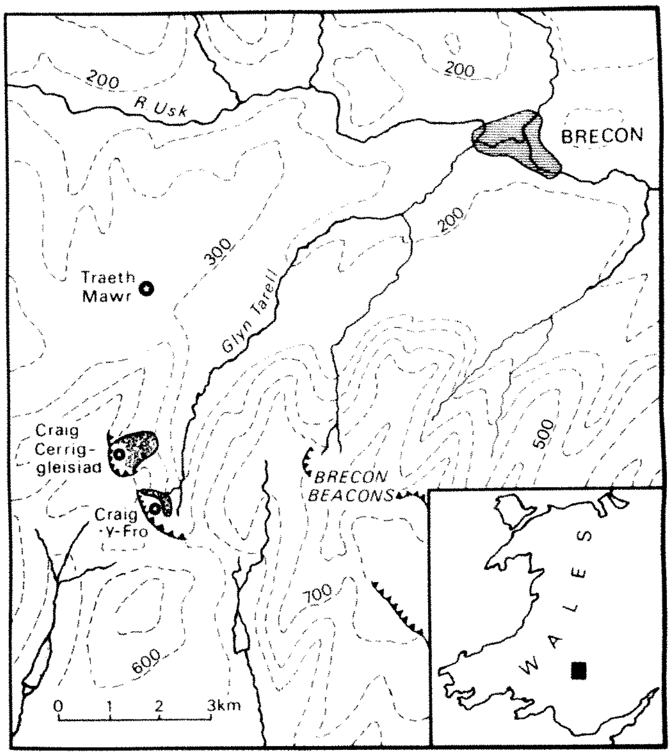

Fig. 3 Stratigraphies, pollen assemblage zones and radiocarbon-dated horizons at the three sites. 1, Fine silt/clay; 2, coarse silt/sand; 3, gravel; 4, gyttja.

At the two sites within the moraines, only Flandrian sediments are present. Lithostratigraphically, the sites are very similar (Fig. 3), the absence of Late-Glacial Interstadial sediments clearly implying that both basins contained glacier ice during the Loch Lomond Stadial. The lowermost organic muds at Craig-y-Fro are characterized by high frequencies of Gramineae and *Juniperus* pollen, and by a rising curve for *Betula*. Similar pollen assemblages are found in the basal sediments at Craig Cerrig-gleisiad, except that low values for *Juniperus* are initially recorded in that profile. The lowermost organic deposits at the two sites within the moraines can therefore be correlated biostratigraphically with the early Flandrian sediments at Traeth Mawr.

A radiocarbon date of 10,030 ± 100 BP (SRR-1563) was obtained from the basal organic sediments at the deepest point in the Craig-y-Fro basin, a date which agrees well with SRR-1560 at Traeth Mawr. At Craig Cerrig-gleisiad, however, the lowermost gyttja deposits were dated at 10,860 ± 70 BP (SRR-1564). This is over 800 yr older than dates obtained from comparable stratigraphic horizons at the other two sites, and is also much older than dates on the Late-Glacial–Flandrian boundary from elsewhere in Britain. The bedrock around Craig Cerrig-gleisiad is old red sandstone, and there are no known outcrops of calcareous bedrock on the northern side of the Brecon Beacons escarpment. The $\delta^{13}C$ value for the dated sample (Table 1) lies within the 'normal' range for gyttja material currently observed from European localities[29], and thus the possibility of contamination by older carbon would seem to be remote. On the other hand, all rocks are known to contain some elementary carbon which can become incorporated into, and concentrated in, gyttja sediments which are accumulating in areas of newly deglaciated terrain[18]. Moreover, it has recently been argued that the $\delta^{13}C$ value on radiocarbon dates from lake muds can no longer be regarded as a reliable indicator of 'hard water error' in view of the polygenetic nature of gyttja material[18,30]. Clearly, therefore, the possibility of a hard water factor in the basal date from Craig Cerrig-gleisiad cannot be excluded, although it is unclear why this should be so when a seemingly 'reliable' date was obtained from a comparable biostratigraphic horizon in the nearby Craig-y-Fro profile (a site located on the same bedrock and with a very similar glacial history).

With the exception of the date from Craig Cerrig-gleisiad, the pollen-stratigraphic and radiocarbon evidence suggests the following sequence of Late-Glacial events. Wastage of the late Devensian ice sheet left the large dead-ice hollow of Traeth Mawr which accumulated organic sediments throughout the mild Late-Glacial Interstadial. Climatic deterioration at ≃10,600 BP led to the break-up of the Interstadial vegetation cover, minerogenic inwash into the Traeth Mawr basin and the recrudescence of small glaciers in the lee of the Brecon Beacons which built moraines beneath Craig-y-Fro and in the cirque of Craig Cerrig-gleisiad. Climatic amelioration at, or shortly before, 10,000 BP prompted the rapid disappearance of these glaciers, the cessation of minerogenic inwash at Traeth Mawr, the onset of organic sediment accumulation in all three basins and the beginnings of Flandrian plant succession.

This research was financed by the British Geomorphological Research Group, and the radiocarbon dates were provided by the Natural Environment Research Council. I thank Dr D. D. Harkness for processing the radiocarbon samples, and Mr A. P. Donald, Mr D. John, Dr D. A. Kirby, Mrs G-M. Kirby, Mr A. Tolley and Mrs M. A. R. Walker for assistance with the fieldwork.

Pliocene dispersal of the horse *Equus* and late Cenozoic mammalian dispersal events

Everett H. Lindsay*, Neil D. Opdyke† & Noye M. Johnson‡

*Department of Geosciences, The University of Arizona, Tucson, Arizona 85721
†Lamont-Doherty Geological Observatory, Columbia University, Palisades, New York 10964
‡Department of Earth Sciences, Dartmouth College, Hanover, New Hampshire 03755

The Cenozoic history of land mammals is marked by brief periods of intercontinental dispersal, termed dispersal events[1,2]. One of these dispersal events includes the horse *Equus*, that evolved in North America, dispersed to the Old World in the Pliocene, and became a prominent member of Old World Pleistocene communities. *Equus* was derived from a species of the single-toed horse *Pliohippus*, known only from North America[3]. Timing for the Pliocene dispersal of *Equus* into Europe was questioned[4] following resolution for the appearance of *Equus* into the Siwalik sequence of Pakistan[5]. It seems that there were at least three major dispersal events of large mammals during the Pliocene (at 1.9, 2.6 and 3.7 Myr). We now report new data that limit the time of *Equus*' dispersal and into Europe to the 2.6 Myr dispersal event.

Development of the magnetic polarity time scale[6,7] and its application in magnetostratigraphy[3,8,9] has provided an independent and world-wide time frame for comparison of land mammal dispersal events, and their placement relative to geological events. Figure 1 shows the magnetic polarity time scale for the last five million years, with several North American late Cenozoic biostratigraphic faunal datum events. These biostratigraphic faunal datum events mark the earliest known records for these mammals (such as *Equus*) that dispersed between North America and Eurasia during the late Cenozoic.

Magnetostratigraphic work in Idaho[3] and Washington[10] documents the first occurrence in North American deposits of at least five genera of land mammals (*Trigonictis*, *Satherium*, *Parailurus*, *Ursus* and *Bretzia*) whose ancestry and/or an earlier record occurs in Palaearctica[11–15]. These immigrants are first recorded in North America during the interval of 3.5 to 4.0 Myr during the upper part of the Gilbert magnetic chron. The appearance of this diverse group of Palaearctic immigrants suggests this interval was a major period of land mammal dispersal between North America and Eurasia.

Early Villafranchian faunas lacking *Equus* and *Elephas* (actually the genus *Mammuthus*) are recognized as chronologically significant[16]. Villafranchian land mammal age includes mammal zones MN 16 and 17 (ref. 23) and a pre-E-L-E Villafranchian interval (mammal zone MN 16a) has recently been established[17]. Previous divisions of early Villafranchian faunas[18] tended to include faunas with *Equus* and *Mammuthus* for example, Montopoli in Italy and Malusteni in Romania with faunas lacking those genera (for example, Triversa in Italy and Etouaires in France). The Etouaires and overlying Roccaneyra faunas of France are placed in mammal zone MN 16b by Mein[17]. *Equus* occurs in the Roccaneyra fauna, but is absent from the Etouaires fauna. The early Villafranchian Vialette fauna in France is comparable to that of Etouaires[19], with both *Equus* and *Mammuthus* absent. The Vialette fauna is overlain by a basalt dated 2.6 Myr (ref. 20) and is underlain by a basalt dated 3.3 Myr. Radiometric results from Etouaires, Roccaneyra and Vialette suggest that the European E-L-E fauna datum (the beginning of mammal zone MN 16b) approximates 2.5 Myr, near the Gauss/Matuyama magnetic chron boundary.

To resolve the correlation of faunas in mammal zone MN 16, and to clarify the European E-L-E faunal datum, we collected palaeomagnetic samples during the summer of 1979 from stratigraphic sections in Italy yielding the Montopoli and Triversa faunas. Each locality was sampled at five sites, with three samples per site. The samples from the Montopoli section span 32 m, those from the Fornace RDB (Triversa fauna) section span only 13 m. All samples were subjected to both alternating field and thermal magnetization to remove secondary components of magnetization.

The section at Montopoli is very sandy and exposures are poor. Strata suitable for palaeomagnetic sampling were found only after diligent search. Calcareous concretions were sampled at the stratigraphically higher sites. All samples gave natural remanent magnetization (NRM) directions of normal polarity, and a.f. demagnetization did not produce any change in the polarity. Partial thermal demagnetization was attempted on the upper three sites, and pilot samples from the upper two sites changed to reversed polarity very suddenly between 550 and 600 °C. The intensities of these samples were very low, approaching the limits of sensitivity of the magnetometer. Then all remaining samples were thermally demagnetized at 500 °C, at which point the other samples from the upper two sites changed to reversed polarity (although the intensity was very low) with polarity of remaining samples unchanged. The resulting polarity zonation (Fig. 2) is weak because of limitation imposed by the available lithology. However, it is the most reasonable polarity interpretation likely to become available from that section.

The section at the Fornace RDB quarry at Villafrance d'Asti provided finer grained lithologies and stronger magnetic properties but the section available for sampling is shorter. Poorly indurated sandstones occur above and below the sampled section at the Fornace RDB quarry. After a.f. and thermal demagnitization, four of the five sites gave unquestionable reversely magnetized polarity (Fig. 2). The directions from the second highest site gave normal polarity after thermal demagnetization to 500 °C. This site apparently records a normal event within an otherwise reversely magnetized section (Fig. 2).

The Montopoli section is interpreted to represent the upper Gauss and lower Matuyama magnetic chrons, with the boundary occurring about 25 m above the base of the section, 7 m below the top of the section which is the level of the Montopoli fauna. The quarry that yielded the Montopoli fauna was relocated by A. Azzaroli with the help of residents of Montopoli. Our highest palaeomagnetic site is from the level of the quarry, 15 m distant along strike.

The Fornace RDB section is interpreted to represent the middle of the Gauss magnetic chron, with a record of the Mammoth and Kaena events, separated by a normal magnetozone. The level of mammals recovered from the Fornace RDB quarry approximates the middle of our section. The Arondelli quarry is about 1.5 km distant across the Triversa valley at the same level as the upper part of our section. Azzaroli[21] correlated the Arondelli and Fornace RDB sections as approximately equivalent. Lithology at the top of our Fornace RDB sampled section is similar to that at the Arondelli quarry. Therefore, the Triversa fauna (based on the Fornace RDB and Arondelli quarry assemblages) is placed in the middle to upper half of our Fornace RDB section, which we correlate with the middle of the Gauss magnetic chron. The polarity zonation of the Fornace RDB section is not definitive for that specific chronological interval; it could represent the Gilbert magnetic chron or the lower Matuyama magnetic chron. Both of those interpretations are rejected, based on faunal similarity of the Triversa fauna with the Etouaires and Vialette faunas of France, and radiometric dates associated with those faunas.

Correlations of the Montopoli and Fornace RDB sections with the magnetic polarity time scale are made with reservation. Interpretations are insecure due to low magnetic intensity of samples from Montopoli, and shortness and non-definitive polarity of the Fornace RDB section. Placement of these sections (and faunas) relative to the magnetic polarity time scale is based as much on biochronological correlation of the faunas as on magnetic polarity zonation.

Magnetic polarity zonation of the Fornace RDB section could have been correlated with the lower Matuyama magnetic chron, which would place the Triversa fauna approximately at the Olduvai event. This correlation is rejected because the Triversa fauna should be earlier than the Montopoli fauna which we correlate with the base of the Matuyama magnetic chron. Faunal similarity of the Montopoli and Triversa faunas is strong, the most significant difference between these faunas is the presence of *Equus* and *Mammuthus* in the Montopoli fauna and their absence from the Triversa fauna. The Triversa fauna is rich and diverse; it includes large mammals like *Tapirus*, *Dicerorhinus*, *Mammut*, and *Anancus*[21,22], which are distinct from but comparable in size to *Equus* and *Mammuthus*. If those latter genera had lived in the Po Valley of Italy during the time the sediments that yielded the Triversa fauna were deposited, they would surely be recorded in the fauna.

The Fornace RDB section could also have been correlated with the Gilbert magnetic chron. This correlation is rejected because of an unpublished palaeomagnetic section from the Pichegu quarry about 30 km south of Nimes, France, that supports a correlation of mammal zone MN 14 (earlier than MN

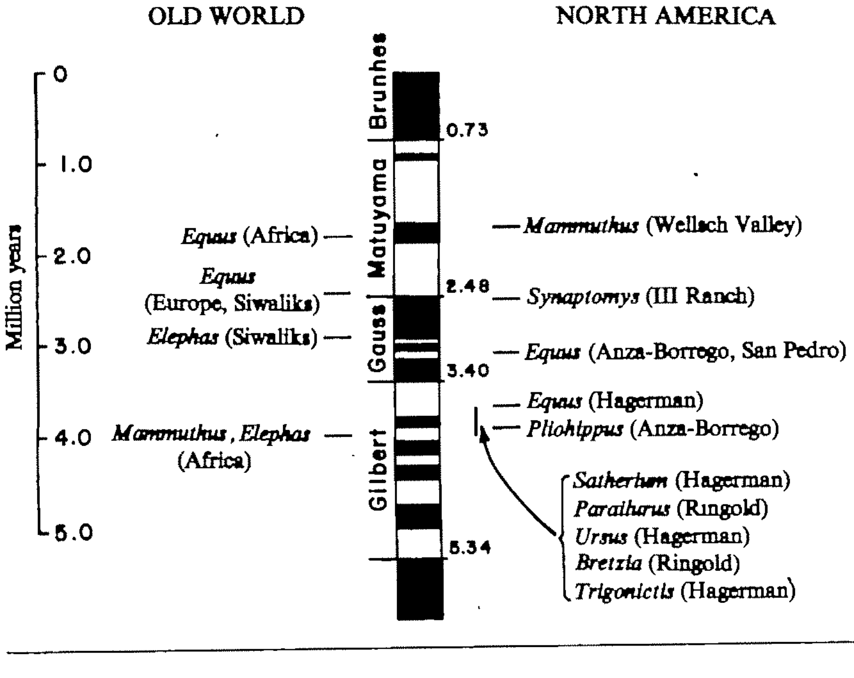

Fig. 1 Important mammalian faunal datum events relative to the dispersal of *Equus*. The central column represents the magnetic polarity time scale (black equals normal polarity and white equals reversed polarity); the Olduvai event is the normal polarity interval at about 1.9 Myr, the Kaena and Mammoth events are the reversed polarity intervals above and below the 3.0 Myr normal polarity event. North American datum events are given for the lowest stratigraphic record of that taxon at the location given in parenthesis. With the exception of *Pliohippus* at Anza-Borrego and *Equus* at Anza-Borrego and San Pedro, the North American faunal data probably represent the earliest North American record for those genera. Old World faunal datum events are believed the earliest known record for those genera on that continent. All faunal datum events are dispersal events with the exception of *Equus* at Hagerman and *Mammuthus* plus *Elephas* in Africa, which are probably evolutionary events. The European E-LE-E (*Equus-Leptobos-Elephas*) faunal datum is placed at the *Equus* faunal datum for Europe and the Siwaliks, at the base of the Matuyama magnetic chron, about 2.5 Myr.

16) with the Gilbert magnetic chron. Suc[24] showed that the palynological extinction of plants of the group Taxodiaceae occurs in southern France during the Pliocene, between the small mammal subzones of Hautimagne and Sete. This chronological interval is approximately at the boundary between mammal zones MN 14 and 15. Suc identified the extinction of Taxodiaceae near the top of the Pichegu section (personal communication), which means the main part of that section is correlative, more or less, with mammal zone MN 14. The Pichegu section, which lacks mammals as it is dominantly marine, is reversely magnetized through an interval of more than 50 m stratigraphically below the extinction of Taxodiaceae. We interpret this long magnetozone of reversed polarity, that corresponds broadly with mammal zone MN 14, as part of the Gilbert magnetic chron. Only the Gilbert magnetic chron in the interval of Ruscinian land mammal age (mammal zones MN 14 and 15) has a monotonously uniform reversed polarity zone of that thickness. Therefore, it seems unlikely that the Fornace RDB fauna, in mammal zone MN 16a, is correlative with part of the Gilbert magnetic chron.

These preliminary results, and our interpretations, support a correlation of mammal zone MN 16 with the late Gauss and early Matuyama magnetic chrons, and suggest the division of MN 16a and 16b approximates the Gauss/Matuyama boundary, 2.48 Myr.

Azzaroli[21] believes that the record of *Equus* and *Mammuthus* from Montopoli is the most primitive and probably earliest record of these mammals in Europe. Thus the appearance of *Equus* and *Mammuthus* in Europe is approximately coincident with their appearance in southern Asia[5] at about 2.5 to 3.0 Myr. Several early Villafranchian faunas in eastern Europe also have early records of *Equus* and *Mammuthus*, and might be as early as, or earlier than, the Montopoli fauna[25,26]. Biochronological-palaeomagnetic sequence studies[27] of the Ponto-Caspian Basin show the beginning of the *Archidiskodon* Superzone (equivalent to the appearance of *Mammuthus*, and possibly *Equus*) at the Mammoth event (about 3.1 Myr) in that area. Extensive Plio-cene–Pleistocene palaeomagnetic studies have been undertaken in southern Tajikistan (near the Russian-Afghanistan border[28] where the Navrukho fauna includes the elephant *Mammuthus* (*Archidiskodon*) *gromovi* (also recorded from Montopoli) and *Equus*. The Navrukho fauna is from rocks with reversed magnetic polarity correlated with the lower Matuyama magnetic chron, and is therefore similar in age to the Montopoli fauna.

Our work in Pakistan[5] demonstrated the appearance of *Equus* and *Mammuthus* in the Oriental zoogeographic region in the late Pliocene (see Fig. 1). We questioned the appearance of these immigrant genera in Europe about one million years before their arrival in southern Asia, but found no definitive data to reject this hypothesis[4]. Results and interpretations given above suggest the coincident appearance of *Equus* and *Mammuthus* in Europe no earlier than about 2.5 Myr.

Equus could not have dispersed before about 3.7 Myr when it evolved from *Pliohippus*; its population density and distribution were probably not sufficient to disperse to Eurasia during the interval 3.7–4.0 Myr, when several Eurasian mammals dispersed to North America. *Equus* became widespread and prominent in the North American faunas after about 3.3 Myr but conditions for dispersal to Asia were apparently not favourable until about 2.6 Myr, shortly before the lemming *Synaptomys* appeared in North America. *Synaptomys* is considered an immigrant to North America and its North American appearance is near-coincident with the south Asian and European appearance of *Equus* (2.5 Myr). Thus, the dispersal history of *Equus* and *Synaptomys* suggest dispersal between North America and Asia about 2.6 Myr.

The discontinuous, sudden, and short duration of these late Cenozoic dispersal events suggests they may be controlled by geological and climatic factors rather than by biological factors. The dispersal history of elephants is similar and supports the concept of more or less widespread and short dispersal events. Elephants evolved in Africa where *Elephas* and *Mammuthus* (*Archidiskodon*) evolved from *Primelephas* at ~4 Myr. *Elephas* dispersed to southern Asia at ~2.9 Myr, slightly before the appearance of *Equus* in southern Asia[5] and the appearance of *Mammuthus* (*Archidiskodon*) in Europe is approximately coincident with the European appearance of *Equus*. The earliest known record[29] of *Mammuthus* in North America is approximately 1.8 Myr. Apparently *Mammuthus* did not enter North America and *Equus* did not enter Africa during the 2.6 Myr dispersal event, because these immigrant populations were too small to warrant further dispersal during that dispersal event. About 1.9 Myr ago, geological and climatic conditions were right for another dispersal event. At that time *Mammuthus* dispersed to North America and *Equus* dispersed to Africa.

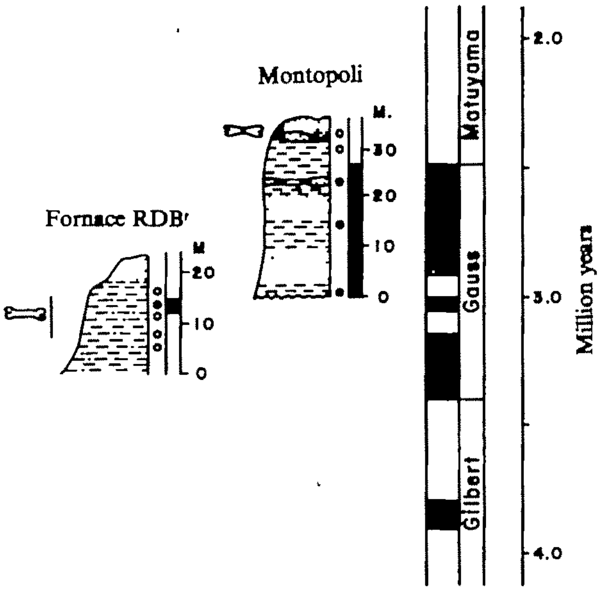

Fig. 2 Magnetic polarity zonation for sections at Montopoli and Fornace RDB quarry (Villafranca d'Asti) in Italy, and correlation of these sections with the magnetic polarity time scale. The Kaena and Mammoth events occur above and below the 3 Myr normal polarity interval. Palaeomagnetic sample sites are shown adjacent to lithologic sections; black circles indicate normal polarity, white circles indicate reversed polarity sites. Location of the Montopoli and Triversa (at Fornace RDB) faunal levels are indicated by bone symbols. The Montopoli fauna is a principal reference for mammal zone MN 16b, with *Equus* present. The Triversa fauna is a principal reference for mammal zone MN 16a, with *Equus* absent.

The earliest datable occurrences of *Equus* in Africa[30] are below the KBS Tuff in the Koobi Fora Formation in Kenya and in member G of the Shungura Formation in Ethiopia. The revised date for the KBS Tuff is 1.81 Myr (ref. 31). The palaeontological evidence (primarily stage of evolution in several lineages of suids) indicates a strong correlation between the KBS Tuff level of the Koobi Fora Formation, member G or H of the Shungura Formation, and Bed 1 of Olduvai Gorge[32–36]. There is a strong palaeontological and radiometric correlation of these units in the interval of 1.8–2.0 Myr. Thus, the appearance of *Equus* in Africa and the appearance of *Mammuthus* in North America may be coincident. We regard the proximity of these appearances as a significant mammal dispersal event, at about 1.9 Myr.

In summary, it appears the horse *Equus* and the elephant *Mammuthus* evolved at approximately the same time in North America and Africa, respectively, and their dispersal to Eurasia was approximately at the same time. Neither is definitely recorded from Europe or Asia prior to about 3.0 Myr, and both are commonly recorded in fossil deposits of both continents younger than 2.5 Myr. Each genus later dispersed to the continent where the other evolved, but is not recorded on that continent until about 1.9 Myr. Additional data are needed to resolve their appearance in Europe in the interval 2.6–3.0 Myr. The dispersal records and timing of dispersal for these two genera serve as a model for late Cenozoic intercontinental dispersal of land mammals. They suggest that the history of mammals during that interval is marked by infrequent, widespread, and comparatively short intervals of intercontinental dispersal. Timing for three of these major dispersal events is approximately 1.9, 2.6, and 3.7 Myr. The nature and timing of these major dispersal events suggest they may be triggered by geological or climatic factors.

Somatic embryogenesis from *Sorghum bicolor* leaves

Wolfgang Wernicke & Richard Brettell

Friedrich Miescher-Institut, PO Box 273, CH-4002 Basle, Switzerland

Plant regeneration from totipotent cultured cells or protoplasts is a prerequisite for the often proposed genetic modification of plants through somatic cell genetics, and has been achieved in many species. The cereals (and the rest of the Gramineae) have, however, proved to be extremely unresponsive to *in vitro* culture techniques[1]. The most convenient source of plant protoplasts is the leaf tissue because it allows the isolation of a large, relatively uniform cell population without the necessity of killing the plant. However, despite considerable efforts, sustained cell division has never been obtained from cereal leaf blade protoplasts[2]. Thus, a crucial question arises of whether leaf cells from cereals are actually totipotent and consequently, whether they can be useful for somatic cell genetics. We now report that young leaf tissue of a cereal can express totipotency even to the extent of forming somatic embryos. However, the ability to respond is rapidly lost during leaf maturation. We think that this phenomenon can explain many difficulties faced in cereal tissue culture. Moreover, the leaf culture we describe may help to ascertain whether mature cereal cells are merely no longer competent (in the sense of Halperin[3]) to respond to tested *in vitro* conditions or whether they actually lose their totipotency.

Sorghum bicolor (L.) Moench was chosen for the experiments. (So far, only the variety G522 (Funk Seeds International) found to be responsive in immature embryo and inflorescence culture[4,5] has been tested.) Plants were grown from seed in test tubes in aseptic conditions for 10 days. Leaves of grasses grow from the base, thus exhibiting a gradient in maturation from base to top. Starting about 0.5 mm above the apical meristem (1.5 mm above insertion of the first foliage leaf), leaves were dissected under a stereo microscope into 1.5-mm long sections. The leaf sections were unrolled and cultured individually on MS

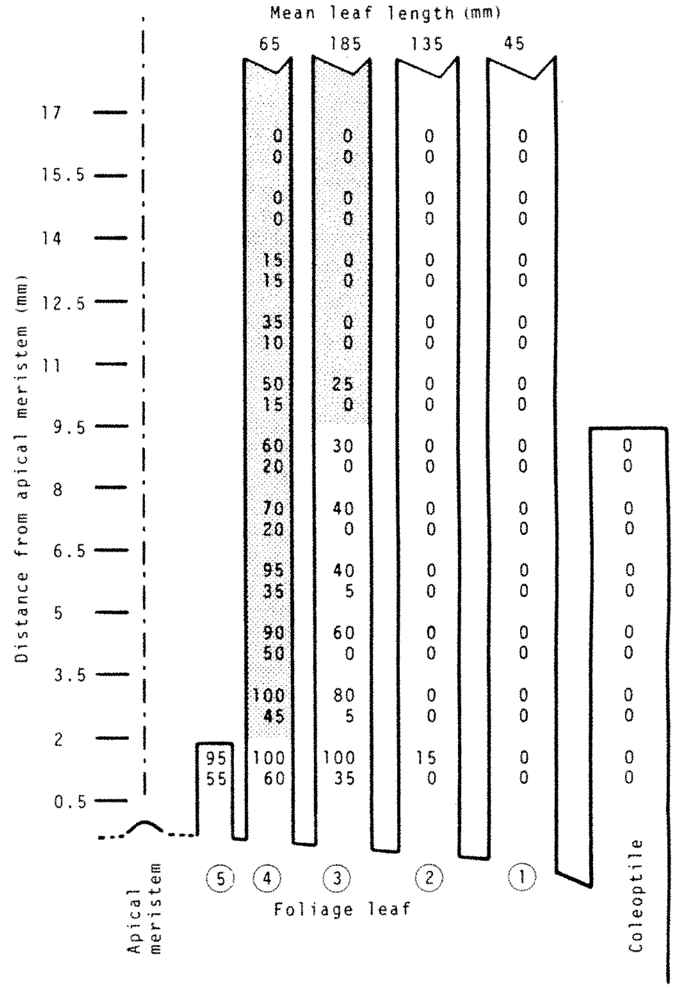

Fig. 1 Diagram of the leaf culture system in *Sorghum bicolor,* showing the response of leaf pieces cultured in the dark at 25 °C. Donor plants were grown from surface sterilized seeds for 10 days on MS medium[6] with 20 g l^{-1} sucrose under 16-h days (light provided by fluorescent tubes, 1,500 lx). Twenty equally sized plants were selected. The lower parts of the plants were cut into 1.5-mm long segments and the leaf pieces were placed individually on MS medium supplemented with 2 mg l^{-1} 2,4-D, 0.1 mg l^{-1} kinetin and 40 g l^{-1} sucrose. The leaf blade was clearly distinguishable from the sheath in the first four foliage leaves and is denoted by the shaded area. The experiments were evaluated after 5 weeks culture. In each segment, upper value: % leaf pieces giving rise to callus; lower value: % leaf pieces with macroscopically visible embryogenic tissue.

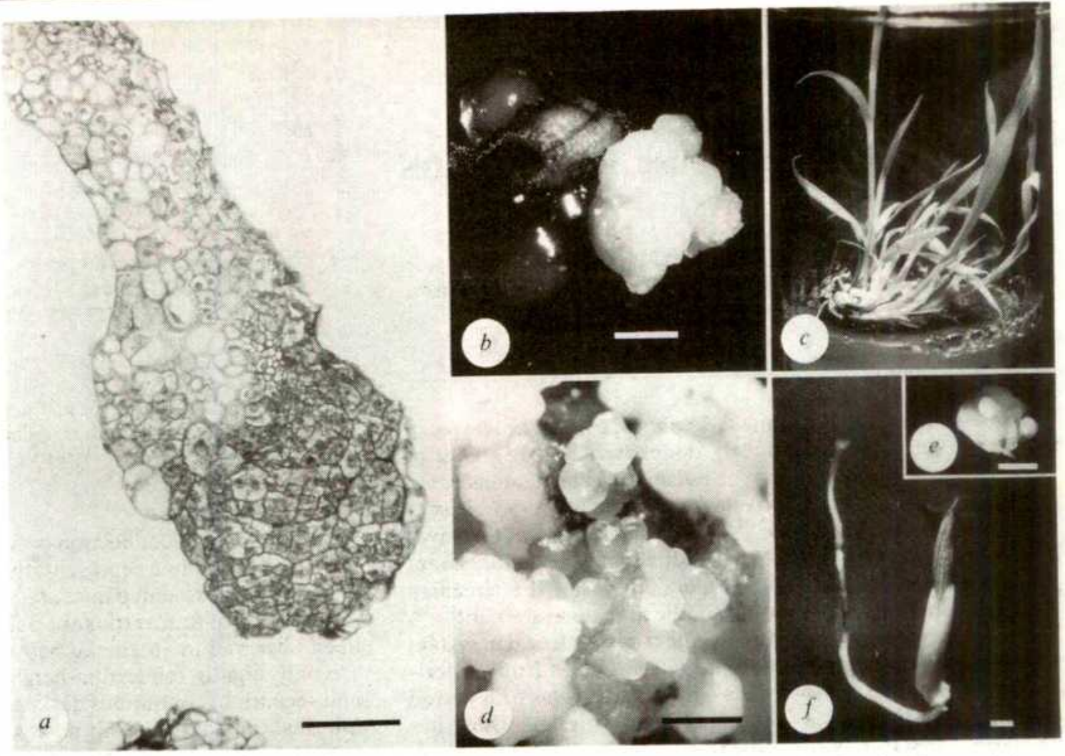

Fig. 2 *a*, Cross-section through a leaf piece (fourth foliage leaf, ~6 mm above the apical meristem) cultured for 5 days on nutrient medium. Note the cell proliferation underneath a region which has been damaged during excision. Scale bar, 100 µm. *b*, Callus growing from a leaf piece (fourth foliage leaf, 14 mm above the apical meristem). The non-proliferating tissue produced a dark pigment. *c*, Plant regeneration in the light (800 lx) from white callus tissue after transfer to auxin-free medium. Shoot growth could be accelerated by addition of 0.1 mg l^{-1} kinetin. *d*, Embryogenic tissue derived from callus shown in *b* after transfer of white compact tissue to a culture medium with reduced 2,4-D concentration. The white globular bodies were able to germinate like zygotic embryos. *e*, Isolated somatic embryo with scutellum, coleoptile and primary root breaking through coleorhiza. Leaf culture origin. *f*, Germinating somatic embryo. In *b*, *d*, *e* and *f*, scale bar, 1 mm.

medium[6]. The youngest leaf that was cultured (fifth foliage leaf) had reached a length of about 2 mm (Fig. 1). In the presence of 2,4-D (1–3 mg l^{-1}) the young leaf pieces proliferated to form a subculturable callus, which consisted for the most part of proliferating yellowish root primordia covered with slimy rootcap-type cells; the roots elongated when 2,4-D was omitted from the medium[7]. In many cases, however, macroscopical examination revealed the presence of a folded, compact, white tissue which, after transfer to auxin-free medium, formed shoots and plantlets (Fig. 2*a*–*c*). Various additions to the medium such as coconut water, casamino acids, cytokinins, different auxins and gibberellic acid (GA_3), were tested. These modifications gave no significant improvement in growth or were even inferior, although the addition of 0.1 mg l^{-1} kinetin seemed slightly to increase the relative proportion of the white tissue. After prolonged culture (~5 weeks), especially after transfer to a culture medium with reduced 2,4-D concentration (0.5 mg l^{-1}), the white tissue formed globular structures (Fig. 2*d*). Many of these structures resembled zygotic embryos in having a scutellum and a clearly defined root–shoot axis. After transfer to a medium without auxin, optionally supplemented with 0.1 mg l^{-1} kinetin, the structures were able to germinate like zygotic embryos (Fig. 2*e*, *f*). In this respect, the leaf cultures did not differ from cultures derived from the scutellum of immature embryos[4].

The response of different leaf pieces is summarized in Fig. 1. It can be seen that the further the 'distance' (spatial and temporal) from the apical meristem, the less responsive the tissue became. This pattern of response correlated with the pattern of leaf blade and leaf sheath maturation described by plant morphologists[8,9].

Cytological examination of cultured immature leaf pieces derived from the fourth foliage leaf revealed that developing mesophyll, bundle sheath and occasionally epidermal cells close to lesions caused by excision were prone to proliferate (Fig. 2*a*). In explants taken from the third foliage leaf, proliferation was more restricted to cells closely associated with the vascular bundles, and resulted in less white, compact tissue (Fig. 1). It seems, therefore, that the embryogenic tissue is formed by mesophyll and/or epidermal cells.

The calluses which have been obtained from immature leaf pieces consist of a mass of proliferating primordia (shoot–embryo and/or root primordia). Full expression of morphogenesis is inhibited by the hormone (2,4-D in this case) essential for stimulation of callus growth, but the primordia can be released by reduction and omission of the hormone. The occurrence of similar responses in morphogenetic cultures of dicots has also been recently discussed[10]. Our findings suggest that the grasses differ from dicots in that the cells have to come from a very immature tissue. In our experiments, totipotent cells were clearly part of the growing leaf blade as well as the leaf sheath, but only in the two least mature leaves. (Root-type callus cultures have been induced from basal (immature) parts of rice leaf sheaths[11].) The recent finding of Saalbach and Koblitz[12], who in a single experiment obtained shoots from a cultured barley leaf, could be explained by proliferation of cells from a leaf that happened to come from close to the apical meristem.

Competence *in vitro* may be correlated with continuing meristematic activity *in vivo*. In fact, in grasses, cell proliferation *in vitro* has only been observed in tissues that are close to an undifferentiated state[13]. Thus, the process which in research on dicots has been termed 'dedifferentiation' has most critical implications for cereal tissue culture. The use of the leaf culture system may enable us to define more precisely the step in differentiation leading to loss of competence (if not totipotency) and thereby possibly overcome the barrier which prevents the mature cells from responding *in vitro*.

We thank Brigitte Bolliger and Stefan Eberhard for technical help and our colleagues for valuable discussions.

Circadian rhythmicity participates in the photoperiodic determination of diapause in spider mites

A. Veerman & M. Vaz Nunes

Laboratory of Experimental Entomology, University of Amsterdam, Kruislaan 302, 1098 SM Amsterdam, The Netherlands

The role of circadian rhythmicity in photoperiodic processes in plants and animals is still poorly understood. Involvement of circadian rhythmicity in photoperiodism has been demonstrated for a number of plants[1,2], two mammals[3,4], a number of birds[5,6], and some species of insects[7–11]. Three theoretical alternatives have been suggested with regard to the form this involvement may take, with emphasis on the possibility that the circadian system is concerned with photoperiodic time measurement[12–14]. Most of the evidence for the involvement of the circadian system in both plant and animal photoperiodism comes from experiments with nondiel photoperiods—light/dark cycles with period lengths other than 24 h. The experimental design which has been used most frequently is the so-called resonance technique, in which the light component of a light/dark cycle is held constant and the dark component is varied over a wide range in successive experiments, to provide cycles with period lengths up to 72 h or more. Rhythmic variations in the photoperiodic response with peaks about 24 h apart are evidence for the involvement of circadian rhythmicity in the photoperiodic process studied. However, in some plants[1], a reptile[15], and a number of insect species[16–20], the resonance technique failed to demonstrate any influence of circadian rhythmicity on photoperiodism. Using the same technique we have now found a rhythmic response in the incidence of diapause in the common spider mite, *Tetranychus urticae*, thus showing that in mites also, circadian rhythmicity is involved in the photoperiodic reaction.

Diapause in *T. urticae* is of the facultative type and occurs normally in adult females which have experienced short-day photoperiods during their larval and nymphal stages of development[21]. The most conspicuous characteristic of the diapause state in *T. urticae* is the deeply orange colour of the diapausing females, as compared with the greenish-yellow of the 'summer' females. Other features of the diapause are arrest of oviposition, cessation of feeding, voiding of the intestinal tract and changes in behaviour. For the experiments, the mites were kept on detached leaf cultures of beans (*Phaseolus vulgaris*). Resonance experiments were performed at 19 °C; photoperiodic cycles consisted of a fixed light phase of 8 h duration and dark phases which were varied over 4–84 h, the duration of darkness being increased in steps of 4 h in the repetitions of the experiment. Approximately 250 mites were used in each photoperiodic treatment and each photoperiodic regime was sustained throughout the complete development of the mites.

The results presented in Fig. 1 clearly show that, with a fixed duration of the light phase, the incidence of diapause in *T. urticae* is a rhythmic function of the duration of darkness. Peaks of high diapause incidence recur with cycle lengths (duration of light plus dark) of about 24, 44, 64 and 84 h. Diapause induction is completely averted in photoperiodic cycles consisting of 8 h light combined with dark phases of 4–9, 24–28, 44–48 and 60–64 h. Apart from the cycles with night lengths of 4–9 h, in all photoperiodic regimes the duration of darkness exceeded the critical nightlength, which is 10 h in the strain of mites used. The conclusion from these experiments is that in *T. urticae* circadian rhythmicity is somehow involved in the photoperiodic determination of diapause. Thus we demonstrate here, for the first time, a functional connection between the circadian system and photoperiodism in a representative of the Acarina or mites.

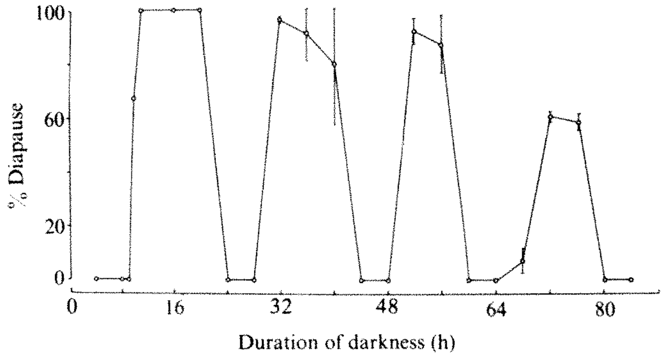

Fig. 1 Diapause incidence in *T. urticae* in cycles of 8 h of light and (abscissa) different durations of darkness. Vertical lines represent ±1 s.e.m.

The results presented here are remarkable in several respects. A sequence of four resonance peaks as shown in Fig. 1 has not been observed in an animal before. The third and fourth peak are only slightly reduced in height in comparison with the first and second. In continuous darkness diapause incidence in these mites is 0% (ref. 21). This means that photoperiodic induction still takes place in cycle lengths of over 80 h. Of these long cycles at 19 °C, only three or four are perceived by the mites during the photoperiodic sensitive larval and nymphal stages. However, previous experiments with *T. urticae* have shown that the summation of photoperiodic information may already be saturated with three photoperiodic cycles[21], which might explain the presence of a fourth resonance peak in the experiments presented here.

Another divergence from the results obtained with other organisms is the fact that the resonance peaks in the experiment with *T. urticae* as shown in Fig. 1 are only about 20 h apart. Resonance experiments with plants, mammals, birds, and insects have shown peak intervals of about 24 h (refs 1–6, 22, 23). If we assume that the peaks of diapause incidence in Fig. 1 result from an influence of the circadian system on the photoperiodic reaction in these mites, the circadian rhythm involved may have a free-running period of only about 20 h. This value is exceptionally low when compared with the values of the periods of all known kinds of free-running circadian rhythms, which tend to be closer to 24 h and normally vary over ~22–27 h (refs 22, 23).

Earlier experiments with *T. urticae*, such as experiments with temperature cycles in continuous darkness[21], with light interruptions in various long nights, and with two light pulses of equal duration in each photoperiodic cycle, could be explained on the assumption that circadian rhythmicity is not involved in photoperiodic time measurement in these mites[24,25]. In work on the fruit tree red spider mite, *Panonychus ulmi*, Lees[26,27] found no indication for the participation of circadian rhythms in the photoperiodic reaction. The divergent results with the two spider mite species are difficult to explain in terms of a mechanism of photoperiodic time measurement. A full account of the results presented here, with considerations on photoperiodic time measurement in spider mites, must await further experiments with nondiel photoperiods in *T. urticae*, which are now under way, and will be published elsewhere.

A test of evolutionary theories of senescence

Michael Rose* & Brian Charlesworth

School of Biological Sciences, University of Sussex, Falmer,
Brighton BN1 9QG, UK

Senescence is the post-maturation decline in survivorship and fecundity that accompanies advancing age. Two main evolutionary theories have been proposed to account for senescence. (1) The mutation-accumulation theory. Deleterious mutations exerting their effects only late in life would tend to accumulate, because of their minimal effects on fitness[1,2]. More precisely, exclusively late-acting deleterious mutations will attain higher equilibrium frequencies under mutation–selection balance than will mutations that act early, resulting in lower mean values for fitness components late in life (ref. 3, p. 218). Medawar[1] emphasized the possibility that this effect would be enhanced by selection of modifiers that postpone the age of onset of genetic diseases. (2) The pleiotropy theory. Williams[4] suggested that many of the genes with beneficial effects on early fitness components have pleiotropic deleterious effects on late fitness components, but are nevertheless favoured by natural selection. (These theories are based on the decline with age in the effect of age-specific fitness-component changes on total fitness[3] (ref. 3, pp. 206–214 and refs 4, 5). Either or both of these theories could apply in any particular population.) Selection experiments in *Drosophila*[6] and *Tribolium*[7] support the pleiotropy theory, although one such experiment gave results that only bordered on significance[8], but the mutation–accumulation theory has never been tested. The present results provide evidence for the pleiotropy theory, but do not support the mutation–accumulation theory.

Tests of evolutionary theories with randomly breeding laboratory populations, as in the present case, require that they be maintained without significant inbreeding after sampling from a long-standing natural population. In August 1975, 400 *Drosophila melanogaster* adults were sampled from the Amherst, Massachusetts, population studies by Ives[9]. There is good evidence that this population has been continuously endemic in the Amherst area since about 1930 (ref. 9). The flies were maintained in the laboratory at 25 °C in 10–16 one-third-pint milk bottles containing Lewis medium and powdered yeast. Discrete generations were used, with 13–15 days from oviposition to adult egg laying. Population size bottlenecks did not occur.

Female phenotypes were assayed as follows. Egg laying counts (24 h) and longevity were recorded from the fourth day of adult life. One male and one female were kept in plastic tubes, under constant illumination at 25 °C, with high-agar charcoal-coloured medium. The surface of the medium was prepared with a yeast paste and a small amount of acetic acid. Daily transfers were performed using CO_2 anaesthesia.

The additive genetic variance (V_A) of a fitness component such as daily egg lay should increase with age if the mutation-accumulation theory is correct. (This is because the additive genetic variance contributed by a di-allelic locus with one allele close to fixation increases with the frequency of the rare allele (ref. 10, p. 135 and ref. 11). The equilibrium frequency of a deleterious allele maintained in the population by recurrent mutation will be higher the later its age of action, if its expression is limited to certain ages[1–3].) Unfortunately, there is a difficult problem concerning the scale on which daily egg lay should be measured so as to test the hypothesis of an increase in V_A with age. Mean daily egg lay shows a senescent decline, from around 70 eggs per day for the first day of assay to about 30 eggs per day

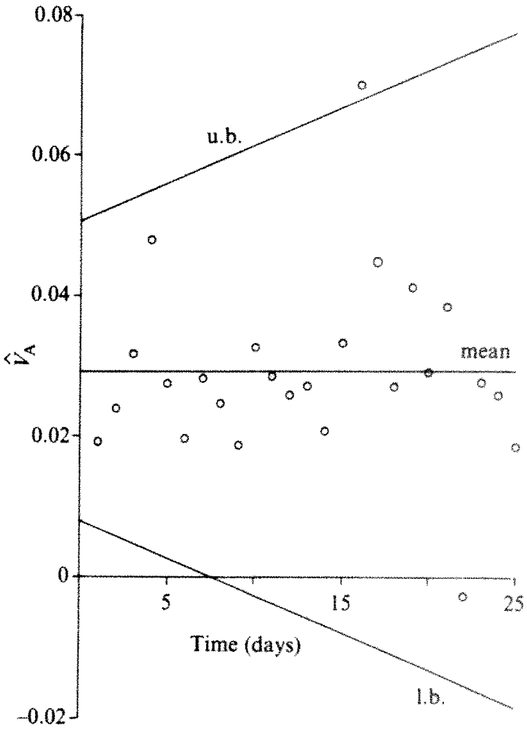

Fig. 1 Estimates of additive genetic variance ($\hat{V}_A$) for egg laying over 24 h. Only data from females which survived the 24 h and laid at least one egg during this period were used, since approximate normality of the data is required for analysis of variance. The data were transformed using the function $x' = \ln(x + 23.81)$, so as to remove the scale effects arising from the fall in egg laying during the 25-day period of assay[12]. The estimates were obtained using a sibling analysis of variance with unbalanced cell allocation (ref. 13, p. 459). The total number of individuals scored falls from 1,099 on day 1 to 396 on day 25. The overall mean for $\hat{V}_A$ during the assay period is 0.02925, which is plotted. The least squares linear regression slope for $\hat{V}_A$ on age has a slope of -0.00002 ± 0.00072, with 95% confidence, which has a t value of -0.0599, with 23 degrees of freedom. This is not significant at any reasonable level of probability. The best estimate for V_A over the period is its mean value. Because of a confounding design variable, confidence intervals for this estimate had to be estimated on an *ad hoc* basis using the normal equations for the unbalanced design[14], giving the upper and lower bounds (u.b. and l.b.) for daily estimates of V_A shown.

for the last day of assay shown in Fig. 1. V_A for untransformed daily egg lay shows a parallel decline. This presumably reflects the fact that a gene with a given effect on fecundity, expressed as a proportion of the population mean, will have a higher absolute effect when the mean is high than when it is low. This suggests the use of a logarithmic transformation of the data. We chose to use the transform $x' = \ln(x + 23.81)$, which removes the relationship between mean and gross phenotypic variance in daily egg lay[12].

Figure 1 shows estimates of V_A on the transformed scale, plotted as a function of age. The upper 95% confidence limit for the regression slope of V_A on age is only 0.0070, whereas the mean of V_A is about 0.0292. There is thus little scope for a substantial increase in V_A with age on the basis of these data. Although the method of transformation used here is a standard procedure in quantitative genetics[12], it is open to the objection that it may disguise a relationship between V_A and age on some other, 'true' scale of measurement. A detailed model of the mutation-accumulation theory, to be presented elsewhere, shows that a roughly threefold rise in V_A on our scale, between first and last day of assay, would be needed to account for the observed decline in mean fecundity. This assumes that the effects of mutations (expressed as proportions of mean fecundity) are similar at different ages. Our results therefore imply either that the mutation-accumulation theory is false, or that the late-acting mutations have much smaller proportional effects on fecundity than early-acting ones.

A test of the alternative theory of pleiotropic gene effects[4] was based on the principle[6–8] that selection for increased reproductive output at later ages should result in decreased fertility at early ages. Figure 2 and Table 1 give the results of an experiment which was contrived so that the effects of selection for late reproduction could be detected at any age. These results show that increases in later reproductive output are associated with decreases in early reproductive output, lowered overall reproductive rate, and increased longevity. This concurs with the predictions of the pleiotropy theory of senescence. Comparable results have been obtained in other experiments on *Drosophila* (see refs 7, 15 and Fig. 7 of ref. 16), although the latter authors favoured an interpretation in terms of maternally transmitted, non-mendelian 'ageing factors'. The increase in late fecundity of flies bred from older parents observed in all three experiments, and the increased longevity of such flies that we have detected, are difficult to reconcile with such an interpretation. The only experiment designed as a critical test for the existence of non-mendelian ageing factors in *Drosophila* (using an inbred line to eliminate genetic variability) yielded negative results[17]. Our data provide two lines of evidence in favour of a conventional mendelian interpretation. First, the analysis of variance of the sibling experiment showed similar values for the between-dam and between-sire components of variance (ref. 10, p. 173) in daily fecundity, so that there was no evidence for maternal inheritance[18]. Second, analysis of the additive genetic correlations between fecundity at different ages, and between fecundity at various ages and longevity, gave several high negative values, broadly consistent with the results of the selection experiments[18]. Thus, there seems little reason to think that our selection responses were due to causes other than selection acting on pre-existing, mendelian variability.

Table 1 Significant differences between samples from the E and L populations of Fig. 2*

Character	L mean	E mean	d.f.	Results of t-test
Five-day total egg laying:				
Assay days 1–5	421.91	551.30	201	−12.364
Assay days 11–15	392.19	323.37	190	4.044
Assay days 16–20	286.69	238.78	165	2.431
Assay days 21–25	182.85	136.79	110	2.515
Longevity in assays days	30.25	26.79	200	2.283
Rate of laying during assay	68.61	76.93	200	−3.327

* $P < 0.05$.

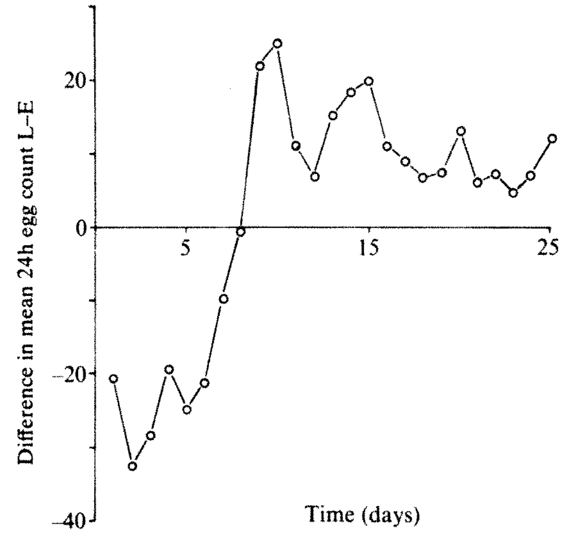

Fig. 2 The ordinate is the difference in mean 24 h egg counts between a sample from a population reproduced at late ages, L, and a sample from a population reproduced at early ages, E. The E population was the base population, maintained as described in the text. The L population was obtained from eggs laid by one generation of the E population. It was then maintained for 12 generations in the same conditions as the E population, but using eggs laid by adults surviving at least 21 days from pupal emergence. Samples of about 100 females were then obtained from each population, and assayed as described in the text. Many of the differences in daily egg-laying shown are statistically significant. Table 1 gives other significant differences between the samples.

We conclude, therefore, that there is genetic variability in female life-history components in *Drosophila*, of the sort postulated by Williams' pleiotropy theory of senescence[4]. This does not, of course, necessarily mean that the established pattern of senescence in *Drosophila* females has been evolved as the result of selection acting on such genes, but this seems likely unless the present properties of genetic variation in *Drosophila* differ radically from those in the past. It therefore seems reasonable to suggest that senescence in *Drosophila* is due to the late-acting deleterious effects of genes which are favoured by natural selection because of beneficial effects at early ages. It does not necessarily follow from this that senescence in all species is due to such pleiotropy. However, that hypothesis is definitely worth testing, in view of the results given here. Articles presenting these experiments in greater detail will appear elsewhere[18].

Chimaeras of *Drosophila melanogaster* obtained by injection of haploid nuclei

P. Santamaría & M. Gans

Centre de Génétique Moléculaire, CNRS, 91190 Gif sur Yvette, France

Since the observation by Bridges[1,2] of a few mosaics containing haploid tissue in *Drosophila*, specimens supposedly haploid have rarely been found[3-5]. A technique for the easy production of haploid animals or tissues could have important applications. We have now successfully designed such a technique by the production of chimaeras obtained by transplantation of haploid nuclei from a maternal effect mutant that produces haploid embryos. We have used this technique to test the proposal of Jack and Judd[6] that the *zeste* locus of *Drosophila melanogaster* cannot repress the activity of unpaired alleles at the *white* locus.

The mutation 1182 described by M.G. *et al.*[7] and by Zalokar *et al.*[8] produces by a maternal effect haploid embryos that never develop into complete larvae. Recently[9], Debec obtained permanent haploid cell cultures from these embryos and also recovered a mutant stock that is fully penetrant at any temperature. We have again checked the characteristics of eggs of this new strain renamed here *maternal haploid* (*mh*). The technique of fixation and staining is as described by Zalokar *et al.*[10]. In 25 young eggs examined (stages 1–4 of Zalokar and Erk[11]), the 3 polar nuclei were found in their normal place in the anterior part of the cortex. Thirteen other eggs were suitable for a karyotypic analysis (stages 9–13) and all showed a set of haploid chromosomes with an X chromosome. From 200 untreated eggs, 183 developed to blastoderm; gastrulation was abnormal and only 22 differentiated further to form embryos with some muscular movements and abnormal segments.

To obtain the chimaeras, two to six nuclei from eggs at stages 10–14 of Zalokar and Erk[11] laid by homozygous *mh* females crossed to $Ki\ e^{11}$ males, were injected into $y\ f^{36a}$; *mwh jv* host eggs at stages 2–8. We used the transplantation technique of Zalokar[12] as described in Santamaría[13]. From 1,046 injected eggs, 429 adults developed, of which 44 had patches of tissue phenotypically $y^+ f^+$; $mwh^+\ jv^+ Ki^+\ e^+$. Twelve more chimaeric larvae died before imaginal differentiation, and were recognized by black mouth parts and bigger, black intersegmental hooks. The fact that all these chimaeras were neither *kinked* nor *ebony* implies that the initiation of mitosis can be triggered by the entrance of the spermatozoon (virgin eggs from *mh* mothers never develop) and that the haploid nuclei can support development at least until the gastrula stage. The phenomenon differs from that in known parthenogenetic *Drosphila* species[14-17] in which a female pronucleus becomes diploid or the products of meiosis fuse and afterwards undergo normal development.

In 24 chimaeras out of the 44, neither cells nor organs of wild-type phenotype were obviously smaller than those of homozygous *mh* females, indicating that the injected nuclei probably diploidize. In fact, in the permanent cell cultures produced by Debec[9] from haploid embryos, some cells diploidize. Moreover, in the Subtenly experiments[18] involving transplantation of nuclei from haploid blastulae into enucleated eggs of *Rana pipiens*, some of them develop into typical haploids and others into homozygous diploids.

Of the 44 chimaeras, 17 showed reduced cell size in all of the donor tissue. In four the organ was smaller than in controls, and in eight the *mh* organ carried more bristles than controls. Some examples are given in Table 1 and Fig. 1. These three modifications were generally found in the same mosaics, but in small patches the size of the organ or the number of pattern elements could not always be distinguished from those of controls.

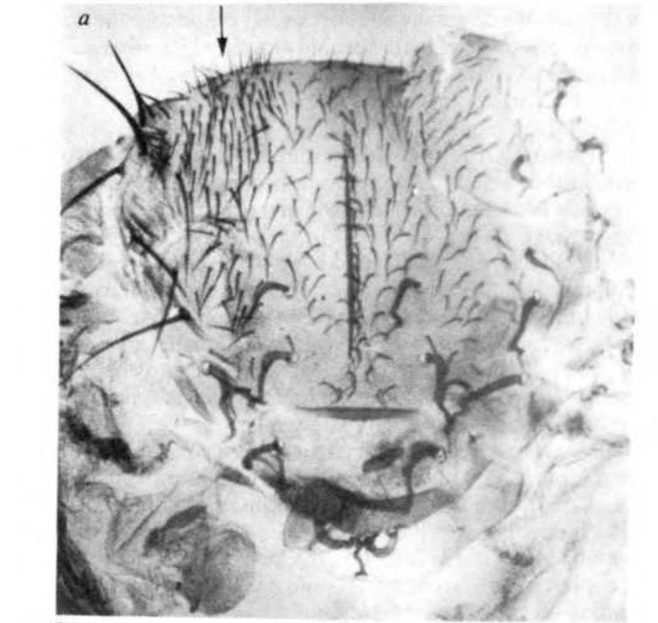

Fig. 1 *a*, Patch of haploid tissue, marked with arrows, in the notum, showing increase in the number of bristles. The host was y, f^{36a}; *mwh jv*. *b*, Normal first leg basitarsus of a *mh* female. *c*, *d*, The first legs of haploid tissue. The basitarsus shows shortening and an increase in the number of bristles. Both were female. *e*, Chimaeric medial triple row formed by reduced, marked with arrows, and normal bristles, both *mh*.

In three more chimaeras in which the size of most of the *mh* cells was normal, a clone also of *mh* cells differentiated in which the bristles were clearly smaller (Fig. 1*e*).

The reduced size of haploid cells and the reduction of organ size are generally found in plants and animals[19], including *Drosophila*[1,2]. However, we believe the variation in the number of elements in the pattern to be new. In *Drosophila*, Held[20] observed a reduction in the number of pattern elements in triploid flies. It is therefore likely that haploid organs woul produce more bristles. As we found chimaeras with the expected characteristics of haploid tissue, it seems reasonable to assume that we are really dealing with haploid differentiation. Moreover, we can argue that the observation of chimaeras with

0028–0836/80/370143—02$01.00

mh tissue in which some cells are normal in size an others small, indicates that some of them became diploid while others did not, therefore excluding the possibility that the small size could be due to other mutations arisen in the strain.

All cuticular regions can be formed by supposedly haploid *mh* cells. However, the fact that complete haploid embryos die implies either that not all embryonic processes can be supported by the *mh* haploid nuclei, or that a maternal effect prevents this development.

Eight chimaeras were formed by *mh* cells in the region of the sex comb. All the chimaeras in the first leg basitarsus were female, but only two had indications of haploidy. Three more chimaeras had a seventh tergite, which is a female characteristic. Our of five *mh* chimaeric genitalia, two were clearly haploid and female, one probably diploid and female, one half male and half female and another one completely male.

Three possible explanations for the maleness are: (1) the formation of X/O; 2A cells, (2) the formation of intersexes 2X; 3A, (3) an ambiguity in the possibilities of differentiation of haploid cells. The well established law of sex determination as a function of the ratio of X to A[21], the fact that X/O males appear in parthenogenetic species[14–17] and the lack of indications of haploidy or triploidy in these chimaeras indicate that the first hypothesis is the most plausible.

If monoploidy of an X is possible, this suggests that monoploidy of a 4th chromosome is also possible in otherwise diploid cells. Haplo-4 tissue would be *Minute* and produce small organs which might be difficult to distinguish from haploid regions. However, haplo-4 individuals never show an increase of pattern elements; also, Minute tissue should either disappear by cell competition[22] or fill an entire compartment when all the cells of the original anlage are of donor origin[23]; this is not the case in most of our haploid chimaeras. Thus, the results presented here indicate that haploid cells can probably develop and differentiate in all the adult cuticular tissue.

Table 1 Comparison between some parameters obtained from 10 homozygous *mh* females and some individual chimaeras

	Control	Chimaeras
Bristles in FLB	105.2 ± 7.7	175, 156
Wing hairs	18.5 ± 2.2	26.4 ± 5.8
Length bristle AP	105.3 ± 4.2	71
Acrosticals	134.3 ± 4.8	156, 195
Bristles in the MTR	93 ± 1.5	77, 73

FLB: first leg basitarsus. Hairs per wing are counted in a square placed in the ocular and between veins L II and L III. Length of the biggest bristle of the anal plate (AP) was measured with an ocular grid. Acrosticals were counted on photographs of the flies. The number of bristles in the medial triple row (MTR) is always reduced in reduced organs probably due to the continuity of elements and as a consequence of the shortening of the wing. In the rest of the organs in which the bristles are interspersed between hairs the phenomenon is the reverse, as in the FLB.

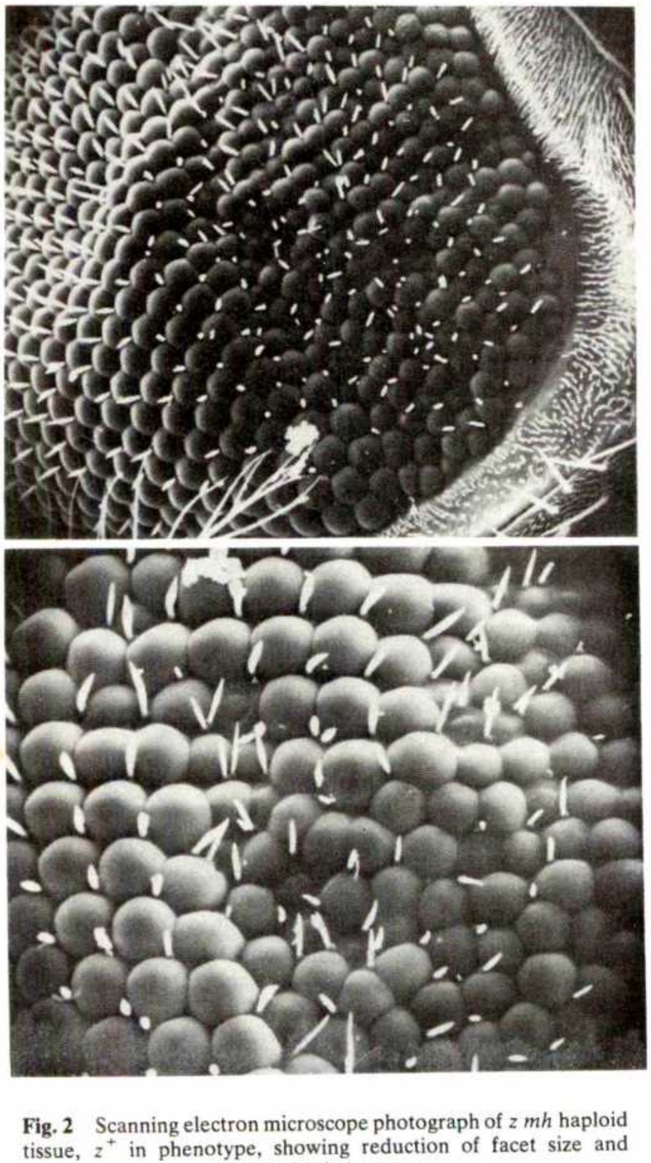

Fig. 2 Scanning electron microscope photograph of *z mh* haploid tissue, z^+ in phenotype, showing reduction of facet size and disturbed bristle pattern.

We hope this technique will prove useful in the analysis of such genetic phenomena as transvection effect, variegation and cis regulation. We have used it to provide new evidence in favour of the thesis of Jack and Judd[6]: in a *zeste* individual, paired *white*$^+$ alleles fail to be expressed while unpaired *white*$^+$ alleles are expressed normally. The repression of *white*$^+$ alleles by *zeste* appears (according to Jack and Judd[6]) to be similar to the transvection described by Lewis[24]. According to this hypothesis, one would predict that haploid *zeste* cells must be *zeste*$^+$ in phenotype. Twenty-two chimaeras were obtained from injection of nuclei from eggs laid by *mh z* females crossed to *Ki e*[11] males into *y w sn* eggs. Eleven of these showed a $y^+\ w^+\ sn^+;\ Ki^+\ e^+$ patch in the eye region: six were *zeste*, four were *zeste*$^+$ and one was *zeste* and *zeste*$^+$. All of the z^+ mosaic areas had reduced cell and organ size (Fig. 2), whereas the *z* areas were normal; therefore, the possibility that the *zeste*$^+$ phenotype is due to the lack of an X chromosome seems unlikely. The fact that the tissue with normal cell size was *zeste* and that tissue with small cells was *zeste*$^+$ provides further support in favour of the haploid nature of the *zeste*$^+$ patches.

We thank Mrs Inge Erk for technical assistance, Drs A. Debec and N. Prud'Homme for criticism and Drs M. Zalokar and P. Simpson for discussions.

Gonadotropin releasing hormone agonists stimulate meiotic maturation of follicle-enclosed rat oocytes *in vitro*

T. Hillensjö & W. J. LeMaire*

Department of Physiology, University of Göteborg,
S-40033 Göteborg, Sweden

Although the principal function of gonadotropin releasing hormone (GnRH) is to stimulate the pituitary gland to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH), there is evidence that agonistic analogues of GnRH directly inhibit steroidogenesis in the testis[1] and ovary[2–5]. On the other hand, Clark *et al.*[6] have demonstrated that GnRH and two agonists have a marked stimulatory effect on prostaglandin synthesis by granulosa cells isolated from immature rats treated with pregnant mare's serum gonadotropin (PMSG). Stimulation by these compounds was distinct from that by LH in that no changes in cyclic AMP production were detected. Thus it seems important to investigate the effect of these peptides on other aspects of ovarian function, for example oocyte maturation. Mammalian oocytes are arrested in the dictyate stage of the first meiotic prophase, and meiosis (oocyte maturation) normally resumes in preovulatory follicles as a consequence of the surge of LH and FSH. This maturation can also be initiated *in vitro* by the addition of gonadotropins to isolated preovulatory follicles[7,8], and is accompanied by an increase in the production of lactate[8]. We now report that GnRH and two potent agonists[9] stimulate meiosis *in vitro* in follicle-enclosed oocytes in a dose-dependent and specific manner, and also cause an increase of lactate accumulation during incubation.

Immature, 26-day-old female rats were injected subcutaneously with 10 IU PMSG (Sigma). After 48 h we isolated the intact preovulatory follicles (8 to 14 from each rat) by microdissection. We incubated them (4 to 7 follicles per flask) in 0.7 ml modified Krebs bicarbonate buffer, with and without test substances, at 37 °C for 2–10 h as described earlier[8]. Following incubation, the medium was frozen for later analysis of lactate content[10], and the oocytes were recovered to determine their stage of meiosis. We examined the living oocytes by Nomarski interference contrast microscopy and in certain cases fixed and stained them according to Donahue[11]. Oocytes were put into one of three categories: (1) immature, with germinal vesicle (GV); (2) maturing, with GV breakdown (GVB); (3) mature, with first polar body (PB). The following test substances were added, as indicated, directly to the incubation media: ovine LH(NIH-LH-S18); synthetic GnRH (LHRH batch 750125, Ferring); [D-Ala^6, des-Gly-NH$_2$]GnRH ethylamide (analogue I, Beckman); [D-Leu^6, des-Gly-NH$_2$]GnRH ethylamide (analogue II, Abbott); TRH Roche (Hoffman-LaRoche); oxytocin (Syntocinon, Sandoz) and somatostatin (batch RAA 14511, Kabi).

In control media, the follicle-enclosed oocytes remained immature, whereas LH, used as a positive control, induced maturation with 99% GVB after 4 h incubation (Table 1). Preliminary experiments failed to show any influence of analogue I on the LH response. Somewhat unexpectedly, GnRH as well as the GnRH agonists added alone were potent stimulators of meiosis (Fig. 1). With GVB as an endpoint, the ED$_{50}$ was 492 ng ml^{-1}, 0.588 ng ml^{-1} and 0.898 ng ml^{-1} for GnRH, analogue I and analogue II, respectively. The time course of maturation induced by analogue I was similar to that induced by LH (Table 1). Analogue I caused complete maturation during 10 h incubation as evidenced by PB formation (Table 1). Synthetic TRH, oxytocin and somatostatin did not stimulate meiosis, indicating the specificity of the effect of GnRH and the agonists (Table 2).

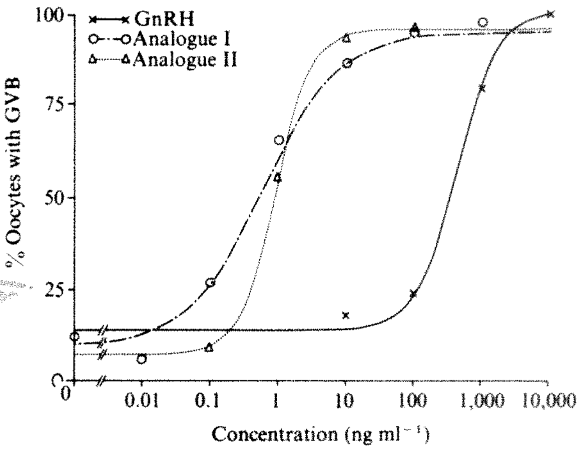

Fig. 1 Dose-response curve of GnRH, analogues I and II on germinal vesicle breakdown (GVB) of follicle-enclosed oocytes incubated for 4 h. The percentage of oocytes with GVB of the total number examined was determined as described in the text. The total number of oocytes analysed were 82, 142, 261 and 141 for control, GnRH, analogues I and II, respectively. Dose–response curves were fitted to the data by computer program using a nonlinear least-squares regression[20].

Although not studied quantitatively, it was clear that GnRH and both analogues also produced dispersal and mucification of the cumulus oophorus, as was previously described for LH and FSH[12].

We also found that lactate accumulation was markedly stimulated by LH (Fig. 2) as reported earlier[8,10]. GnRH, analogue I and II, but not TRH, also enhanced lactate accumulation. The maximal response, however, was considerably less than the maximal response produced by LH. When we tested LH together with analogue I, we did not find any significant additivity.

These data clearly show that GnRH has a stimulatory effect on meiotic maturation of follicle-enclosed rat oocytes. When we initiated these experiments we did not know what results to expect, as GnRH and agonistic analogues have been shown to have both direct inhibitory[2–5] and direct stimulatory[6] effects on different parameters of ovarian function. In our first experiments we found that these substances did not inhibit spontaneous maturation of isolated rat oocytes, nor did they inhibit

Table 1 Time course of meiotic maturation induced by analogue I and LH

	Per cent with GVB		Per cent with PB
	2 h	4 h	10 h
Control	8 (50)	16 (110)	12 (43)
Analogue I	22 (50)	98 (110)	75 (44)
LH	26 (38)*	99 (78)	63 (75)*

Follicle-enclosed oocytes were incubated for the times indicated in absence or presence of analogue I (1 μg ml^{-1}) or LH (1 μg ml^{-1}). Percentage of oocytes with germinal vesicle breakdown (GVB) or first polar body (PB) of the total number examined (in parentheses) was determined as described in the text.

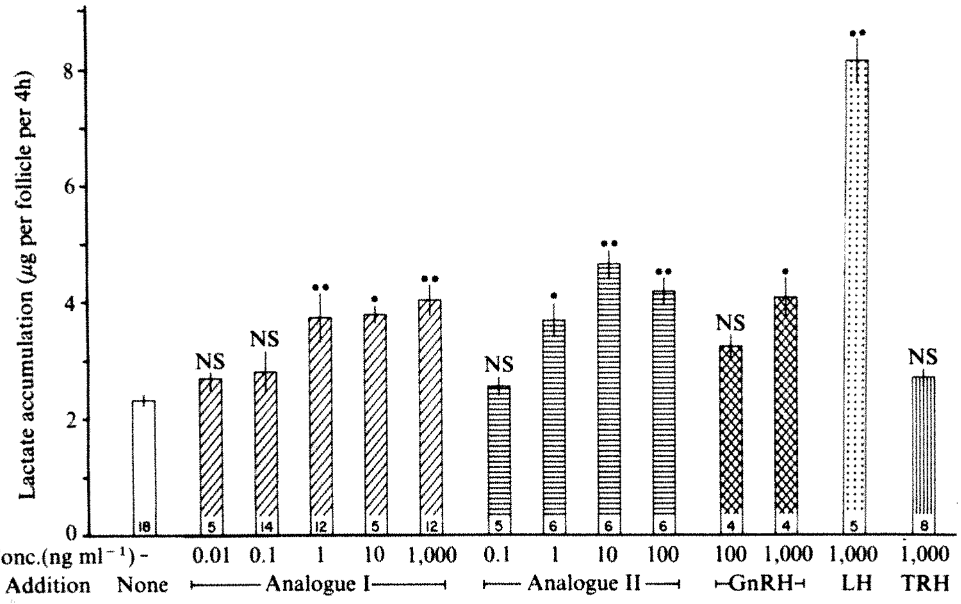

Fig. 2 Effect of LH, TRH and various concentrations of GnRH, analogues I and II on follicular lactate accumulation (μg per follicle) during 4 h incubation. Incubations and lactate measurement were carried out as described in the text. Bar heights represent the means and vertical lines the s.e.m. The number of samples in each group is indicated at the bottom of each bar. Statistical differences between groups were calculated by analysis of variance followed by Student–Newman–Keul's multiple range test. ☐ * $P < 0.05$; ** $P < 0.01$; NS, not significant.

the stimulatory effect of LH on follicle-enclosed oocytes. It was reported recently that GnRH and an agonist produced meiosis and parthenogenetic-like cleavage when injected repeatedly into hypophysectomized diethylstilboestrol-treated rats[13]. Whether the stimulatory effect by GnRH on oocyte maturation has a physiological role, remains to be determined.

Oocyte maturation is normally triggered by LH, but this hormone seems to stimulate meiosis only indirectly through a primary effect on the follicle cells. Although LH stimulates production of follicular cyclic AMP, prostaglandins, steroids and lactate, none of these substances seem to act as meiosis stimulating factors on the oocyte itself[14]. It has been suggested that meiosis is regulated by an intra-follicular inhibitor, the action of which is terminated by LH. An oocyte maturation inhibitor (OMI) has been partially purified from pig follicular fluid and was found to be a peptide with a molecular weight in the order of 2,000 (ref. 15).

The minimal effective dose of GnRH on oocyte maturation in our experiments (0.1 μg ml^{-1}) seems to be far above the possible physiological circulating levels of endogenous GnRH[16]. However, the possibility has been raised that GnRH might be produced locally in tissues other than the hypothalamus, such as placenta[17] and ovary itself[4,18]. If this is the case, then the process of oocyte maturation might be determined partly by a balance of locally formed peptides that may be stimulatory (GnRH) and inhibitory (OMI) in nature.

The mechanism by which GnRH and these two analogues stimulate oocyte maturation also remains to be determined. Clayton *et al.* have shown the presence of specific GnRH receptors in dispersed cells and membrane fractions of luteinized rat ovaries corresponding to a direct action on hormonal stimulation of progesterone and cyclic AMP production[5,19]. The mechanism of stimulation for these peptides may, however, be different from that for LH, as was shown for the stimulation by GnRH of prostaglandin synthesis in rat granulosa cells[6]. Such a concept seems to be supported by our observation that the maximal stimulation of lactate accumulation, obtained by any test dose of GnRH or its two analogues, was well below the maximal stimulation caused by LH. Further detailed studies of the effect of these peptides on other parameters in our incubation of follicle-enclosed oocytes, such as cyclic AMP accumulation and steroidogenesis, might shed light on this problem.

We thank Dr W. F. White (Abbott) for the gift of analogue II, Dr K. Ahrén for support and advice, S. Rosberg for help and advice with the statistical analysis, Mrs H. Thelander for technical assistance and Mrs A-L. Dahl for preparation of the manuscript. This work was supported by grants from the Swedish MRC (No. 05650), and Magnus Bergvalls Stiftelse (to T.H.) and by the NIH (HD08747, to W. J. LeM.). NIH LH-S18 was supplied by NIAMDD. W. J. LeM. is in receipt of a Fogarty Senior International Fellowship (TW00318) and a Visiting Scientist research grant from the Swedish MRC (No. 5732).

Macrocortin: a polypeptide causing the anti-phospholipase effect of glucocorticoids

Geoffrey J. Blackwell*, Rosa Carnuccio, Massimo Di Rosa, Roderick J. Flower*, Luca Parente* & Paola Persico

Institute of Experimental Pharmacology, Faculty of Pharmacy, University of Naples, Via L. Rodino 22, 80138 Naples, Italy

Anti-inflammatory glucocorticoids inhibit prostaglandin (PG) biosynthesis by preventing arachidonic acid release from phospholipids rather than inhibiting the cyclooxygenase[1–16]. As in other cells[17–19], this steroid action depends on receptor occupation and *de novo* protein/RNA biosynthesis[12–16]. We have previously shown in guinea pig perfused lungs and rat peritoneal leukocytes that the effect of steroids on PG generation is mediated by an uncharacterized 'second messenger'[13,16]. Now, we report that this factor (which we have named 'macrocortin') is an intracellular polypeptide whose release and synthesis are stimulated by steroids. Macrocortin derived from rat peritoneal leukocytes is very similar to that released from guinea pig lungs.

Steroids prevent PG generation by rat peritoneal leukocytes[14,16,20] and we established that this was due to the release from the cells of a non-dialysable 'second messenger'[14,16]. In these experiments we found that macrocortin release from leukocytes was induced by hydrocortisone in 'physiological' concentrations (Fig. 1*a*) and that the amount released in the presence of a fixed concentration of hydrocortisone was proportional to the number of cells present (Fig. 1*b*). Analysis of the time course of macrocortin release (Fig. 1*c*) showed that 30 min after adding hydrocortisone, approximately half the total inhibitory activity was released into the medium. By 90 min most inhibitory activity was extracellular, and by 150 min release was virtually complete. Leukocytes incubated with 1 μg ml^{-1} cycloheximide or without hydrocortisone did not release the inhibitor. Steroids release other factors from leukocytes[21]; was macrocortin synthesized *de novo* in response to the hydrocortisone, was it stored and secreted by a steroid dependent process, or did both mechanisms operate? To answer these questions we lysed untreated rat peritoneal leukocytes by repeated (4 times) freeze-thawing and heated them to 70 °C for 5 min to provide some protection from proteolysis. Dilutions of these lysates possessed high inhibitory activity suggesting that at least some macrocortin was stored in cells. Pretreatment of cells with hydrocortisone reduced intracellular macrocortin by 90%.

In further experiments, groups of 20 male Wistar rats (200–250 g) were treated with dexamethasone (Decadron, Merck; 1.5 mg per kg subcutaneously in the flank) or with saline. The amount of macrocortin contained in a known number of peritoneal leukocytes after collection was determined each hour for 4 h (five rats for each time point) and compared to saline-treated controls. One hour after steriod treatment macrocortin was undetectable in the leukocytes ($n = 3$). After 2 h, the macrocortin content of the cells had returned to control levels ($n = 2$), and increasing amounts (2–3 times control levels) of the material were found 3 and 4 h after treatment ($n = 3$). These experiments indicate that in addition to a steroid-induced depletion of macrocortin, there is a further phase of re-synthesis and that this increases the amount of inhibitor above control levels.

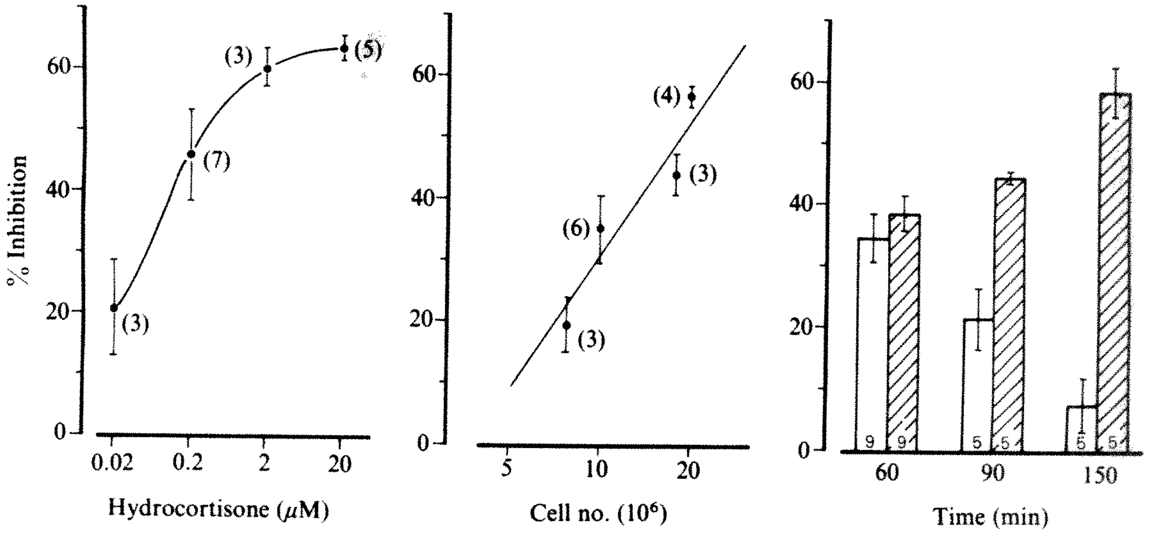

Fig. 1 Male Wistar rats (150–200 g) were killed by exposure to ether. The peritoneal cavity was washed with 20 ml of heparinized Krebs solution and the cell-rich fluid (80% mononucleate and 20% polymorphonucleate) was removed and centrifuged (500 *g*). The cells from 10–15 animals were pooled and washed twice by resuspending in Krebs solution enriched with bovine serum albumin (BSA, 100 μg ml^{-1}). *Release of macrocortin*: The final suspension, usually containing 1×10^7 cells ml^{-1} ('generator leukocytes'), was divided into two samples: hydrocortisone sodium phosphate was added to one sample. No drug was present in the other sample. Both samples were incubated at 37 °C in a metabolic shaker. After incubation, the cells were removed by centrifugation and the supernatants were dialysed overnight against 300 vol Krebs solution at 4 °C. *Assay of macrocortin*: A second pool of freshly collected leukocytes ('test leukocytes') was suspended in Krebs–albumin. A series of 3-ml samples were prepared by mixing 1 ml of cell suspension with 2 ml of dialysed supernatant and incubated for 120 min at 37 °C with killed bacteria (*Bordetella pertussis*) in a ratio of 800–1,000 bacteria per cell. After the incubation the cells were removed by centrifugation and the amount of PGs in the supernatant was determined by bioassay over rat stomach strips using synthetic PGE_2 (Upjohn) as reference standard. Test leukocytes incubated with supernatants collected from steroid-free generator leukocytes released on average 10–12 ng PG (in terms of PGE_2) per 10^6 cells in 120 min. The release was inhibited when the incubation was carried out in presence of dialysed supernatants collected from generator leukocytes treated with hydrocortisone. Results are expressed as mean per cent inhibition (± s.e.m.) of the PG formation by test leukocytes exhibited by various supernatants from steroid-treated generator leukocytes, compared with the PG formation in presence of supernatants from steroid-free generator leukocytes. For other experimental details see refs 14, 16. *a*, Macrocortin release by cells incubated for 90 min with increasing concentrations of hydrocortisone (figures in parentheses indicate numbers of experiments). *b*, Relationship between macrocortin release and number of cells (generator leukocytes) incubated with 20 μM hydrocortisone for 90 min. *c*, Time course of macrocortin release. Cells were incubated with hydrocortisone (20 μM) for different times. At the end of incubation the inhibitory activity present in the Krebs solution as well as within the cells were separately determined. After removing the cells by centrifugation, Krebs solution was collected, dialysed and tested as above (hatched columns). The centrifuged cell pellet was resuspended in an equivalent volume of Krebs solution, disrupted by repeated (4 times) freeze-thawing and centrifuged (100,000 *g* for 60 min). The supernatants were tested for the inhibitory activity as above (open columns). Figures in columns indicate numbers of experiments.

0028-0836/80/370147—03$01.00

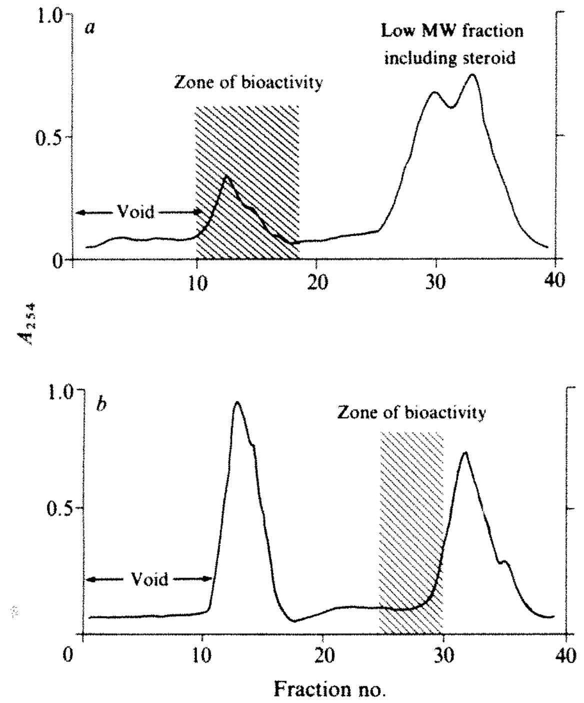

Fig. 2 Partial purification of guinea pig lung macrocortin by Sephadex chromatography. Both columns were 100 × 1 cm, the equilibrating and eluting buffer used in each case was 0.1% ammonium bicarbonate adjusted to *p*H 7.5. The flow rate was 0.8 ml min^{-1} and fractions were collected automatically every 5 min. The UV absorbance at 254 nm was continuously measured with a Uvicord flow cell monitor. For isolation of the lung-derived material, batches of the Krebs solution effluent from steroid-treated lungs were processed in an ultrafiltration chamber fitted with a 500 or 1,000 MW filter. The effluent was concentrated to 100–200 ml and then lyophilized. The residual material was dissolved in 10 ml of buffer and applied to the G-25 (medium) column. Fractions were collected and lyophilized. The biological activity was estimated using lungs treated with cycloheximide (5 μg ml^{-1}) to prevent the effects of the steroid. *a* Shows the results of such an experiment; several UV absorbing peaks were seen; those associated with fractions 10–20 were compounds with a MW greater than the nominal cut-off point of this gel (in this case, 5,000). The UV absorbing peaks which appeared in fractions 25–40 were low MW compounds including the steroid. In one experiment, in which radioactive dexamethasone was added to the crude effluent, all the radioactivity was subsequently recovered in fractions 30–40. There was no trace of radioactivity in the high MW fractions. In contrast, all of the steroid-like bioactivity was recovered close to the void volume. These preparations were free of steroid and buffer salts and could be conveniently lyophilized. This material was rechromatographed on Sephadex G-50 (medium). In this case however, the biological activity was retained by the column and did not emerge until fractions 21–28. Compounds moving with this mobility would have a MW of ~15,000. V_e (ml) BSA, 38.5; trypsin inhibitor, 76.5; macrocortin, 84; cytochrome *c*, 86; dexamethasone, 122.5. Macrocortin production by the lungs was variable. Of all lungs tested, ~15% did not respond to the steroid at all. The inhibitory response to the steroid (thus the production of macrocortin) was enhanced when the glucose concentration in the Krebs solution was increased from 1 g l^{-1} to 2 g l^{-1}. A striking improvement (~twofold) in inhibitory activity was observed when a mixture of 21 amino acids (final concentration of each, ~1 nM) was included in the Krebs solution. Leukocyte-derived macrocortin was prepared as follows: sometimes macrocortin released from cells stimulated by hydrocortisone was used as a starting material, in other instances crude lysates of unstimulated cells were used. In the former case, the medium when separated from the cells was dialysed overnight against 300 vol of Krebs solution at 4 °C before column chromatography. In the latter case, the crude, heat-treated lysates were centrifuged at 100,000 *g* for 1 h to remove coarse debris and precipitated protein. In either case the resulting material was first passed over a Sephadex G-25 column. As with the lung-derived material, bioactivity was found in the void volume and this was rechromatographed on Sephadex G-50. Again, macrocortin activity was retained by the column and eluted with a position indicating a MW of ~15,000. The steroid-induced release of macrocortin from leukocyte incubations was sensitive to the glucose concentration (the amount used here (2 g l^{-1}) is essential for complete release). Vigorous gassing of buffers for more than about 5 min apparently prevented release at the cell density used. The amount of macrocortin found in crude lysates of leukocytes was variable and ~10–20% of preparations contained no detectable material, or very small amounts. At the moment, we cannot gauge the influence of endogenous steroids on the macrocortin content of leukocytes and this could well be a source of variation.

Partially purified macrocortin has been isolated from two sources—the effluent from steroid-stimulated guinea pig lungs, and rat peritoneal leukocytes—see Fig. 2 legend for method. Macrocortin from both sources has an apparent molecular weight (MW) of 15,000 and also has a number of properties in common: both preparations are stable at 70 °C for up to 30 min but are destroyed by boiling. Acidification of the factor to *p*H 2 for 20 min resulted in less than 15% loss of activity. Macrocortin seems to be a protein because lung-derived material lost substantial (40–70%) activity after being stirred overnight at 4 °C with trypsin (10 μg ml^{-1}) or papain (10 μg ml^{-1}). The biological activity of partially purified (ex G50) leukocyte-derived macrocortin was also reduced (60–70%) by incubation for 1 h at 37 °C with 2.0 U of immobilized trypsin (Pierce).

Simple experiments with crude lung or leukocyte macrocortin demonstrated a considerable similarity in their biological activity: phagocytosing rat leukocytes produced less PGs when incubated in effluent from steroid-treated lungs than in effluent from control lungs (3.86 ± 0.53 and 5.63 ± 0.69 ng PGE$_2$ per 10^6 cells; *n* = 7). Krebs solution, in which leukocytes and steroid had been incubated together, inhibited PG synthesis by fresh leukocytes and thromboxane release from the lung[13]. Macrocortin from leukocyte lysates inhibited strongly in both systems. In each type of experiment, boiling abolished, and arachidonate reversed, the inhibition indicating that the inhibitor was heat labile and did not act at the cyclo-oxygenase level. The inhibition was cycloheximide-resistant and could not therefore be due to residual steroid.

Leukocyte-derived macrocortin also inhibited phospholipase activity in the lung as estimated by a radiochemical technique (see Fig. 3). The inhibitory activity was of rapid onset and was abolished by boiling.

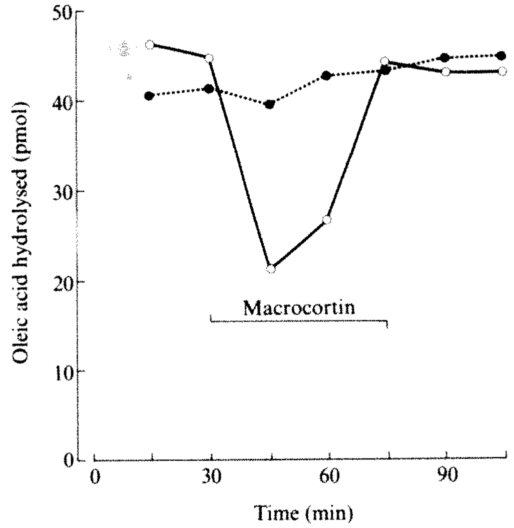

Fig. 3 Inhibition of guinea pig lung phospholipase A$_2$ activity by leukocyte-derived macrocortin. The assay depends on a specifically labelled molecule 1-palmitoyl, 2-^{3}H-oleic phosphatidylcholine. The rationale of the assay, preparation of the isotope and further methodology are described in ref. 11. Briefly, a mixture of the tritiated phosphatidylcholine and ^{14}C-labelled oleic acid (0.1 μCi total), dissolved in Tris buffer (*p*H 7.5), was injected into the Krebs solution entering the pulmonary artery. The effluent was collected for 5 min, 5 ml of Tris buffer (*p*H 7.5; 100 mM) was added to stabilize the *p*H, and the labelled fatty acids were extracted into 5 ml hexane by 1 min vortex mixing. An aliquot of the hexane was transferred into scintillation vials and the solvent evaporated with a gentle stream of nitrogen. Liberation of the ^{3}H-oleic acid from the phosphatide by phospholipase A$_2$ increases the ^{3}H/^{14}C ratio of the extracted fatty acids, enabling percentage hydrolysis to be estimated. The ratio of the two isotopes in a small aliquot of the aqueous solution was also determined: this gave a value for the 'total hydrolysis' and the actual hydrolysis was then calculated. ○, Normal macrocortin (ex G25); ●, boiled material. Lungs had been perfused for 1 h at time '0 min' on the graph. The inhibitory activity was of rapid onset without the latency seen with the corticosteroids.

Arachidonate-derived products such as PGs[22] and 12-hydroxy-5, 8, 10, 14 eicosatetraenoic acid[23] (12-HETE) are involved in the pathogenesis of inflammation. The aspirin-like drugs block the cyclooxygenase[24–26] and this probably explains their therapeutic efficacy. Steroids are without activity on the cyclooxygenase enzyme but potently inhibit PG biosynthesis in viable cells. An important link was established between phospholipase inhibition and steroid action by Gryglewski's group[3] and Danon and Assouline were the first to propose that this was due to an action on the genome[12]. We took this concept further and provided indirect evidence for a second messenger which mediates the anti-phospholipase effects of steroids[13,16]. Here we provide the first direct evidence for such a factor (macrocortin) and have determined that it is a polypeptide of approximately 15,000 MW. In leukocytes steroids cause both a release and re-synthesis of macrocortin—both effects are blocked by inhibitors of RNA/protein synthesis.

Most aspirin-like drugs block only the cyclooxygenase pathway and may potentiate the formation of other arachidonate-derived substances, such as the chemotactic 12-HETE[27] and the bronchoconstrictor slow-reacting substance of anaphylaxis[28]. The steroids differ in this respect and block the formation of all products as they restrict substrate (arachidonate) availability. This may explain why they are able to block cell migration and allergic bronchoconstriction whereas the aspirin-like drugs cannot. In view of the work reported here, we propose that the most likely effector of steroid action on the arachidonate cascade is macrocortin.

Thyrotropin-releasing hormone—CNS action to stimulate gastric acid secretion

Yvette Taché, Wylie Vale & Marvin Brown

Peptide Biology Laboratory, The Salk Institute, PO Box 85800,
San Diego, California 92138

Much physiological and pharmacological evidence has accumulated to suggest that the autonomic nervous system has an important role in the peripheral modulation of gastric secretion[1], although the neurochemical mediators in the brain which initiate or modulate autonomic input are poorly understood[1–4]. Recently, the demonstration that some oligopeptides present in mammalian brain act in the central nervous system (CNS) to influence profoundly glucoregulation[5], thermoregulation[6,7], blood pressure[8,9], sympathetic outflow[9–11], muscular activity of gut[12,13] and stress-induced gastric haemorrhagic lesions[14] have led us to examine a possible role for some of these endogenous brain oligopeptides as chemical messengers involved in the CNS modulation of gastric secretion. We report here that thyrotropin-releasing hormone (TRH) acts within the CNS to elicit a vagus-dependent stimulation of gastric acid secretion.

In this study we used male Sprague–Dawley CD rats (250–300 g) maintained *ad libitum* on Purina Laboratory Chow and tap water, and housed in conditions of controlled temperature and illumination (from 06 : 00 to 22 : 00 h). All experiments were performed according to the same time schedule in 24-h food-deprived rats with free access to water up to the beginning of treatment. Saline or test materials were injected intracisternally (i.c.) or intravenously (i.v.) via the jugular vein under light ether anaethesia, then the pylorus portion of the stomach was ligated. In some experiments, immediately before peptide injection and pylorus ligature, subdiaphragmatic vagotomy or sham operation was performed using the general method described by Martin *et al.*[15]. Conscious animals were decapitated at various intervals following pylorus ligature and gastric content was collected. Gastric volume and pH were measured and samples (0.5 or 1 ml) analysed for gastric acidity by titration with 0.01 M sodium hydroxide to a pH of 7.0.

Peptides, synthesized by Dr J. Rivier using solid phase methodology[16], and atropine sulphate were freshly dissolved in 0.9% saline before use and injected i.c. in 10 µl or i.v. in 0.2 ml volume. Following analysis of variance, differences between groups were determined by the multiple range test of Dunnett and Duncan using the computer program EXBIOL.

TRH given i.c. induced a marked elevation in the volume, titratable acid concentration and output of gastric secretion (Table 1). The time course of gastric response to TRH (expressed as percentage of changes compared with control decapitated at the same time period and taken as 100% change) indicated that the stimulatory effect of TRH reached a maximum within

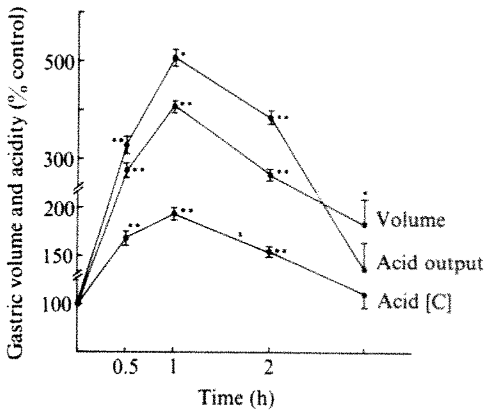

Fig. 1 Temporal effect of TRH (1 µg, i.c.) on gastric secretion. Twenty-four-hour fasted rats were injected with saline or TRH, then the pylorus was ligated and groups of saline and TRH-treated rats were decapitated at 30 min, 1, 2, or 3 h post-treatment. Each curve represents changes in gastric secretion induced by TRH injection, expressed as percentage compared with control groups taken for each time period as 100% change. $*P<0.05$; $**P<0.01$ as compared with saline-treated group decapitated at the same time period post-injection.

Table 1 Gastric secretory response to i.c. injection of TRH and TRH analogues

Peptide	No. of rats	Volume (ml per rat)	*p*H	Gastric secretion Titratable acidity Concentration (mequiv. l^{-1})	Output (μequiv.)
Saline	7	2.1±0.5	1.87±0.09	61±9	154±65
TRH	7	5.3±1.0*	1.51±0.05†	95±9†	551±134*
[^{3}Me-His^2]-TRH	7	4.9±0.8*	1.51±0.03†	88±8†	464±111†
[^{1}Me-His^2]-TRH	8	1.6±0.4	1.71±0.11	69±7	130±44

24-h fasted rats under light ether anaesthesia were injected i.c. with saline (10 μl) or peptides (1 μg per 10 μl) and the pylorus was ligated. After 2 h, the animals were decapitated and gastric secretion collected.
* $P<0.001$; † $P<0.05$ as compared with saline-treated rats.

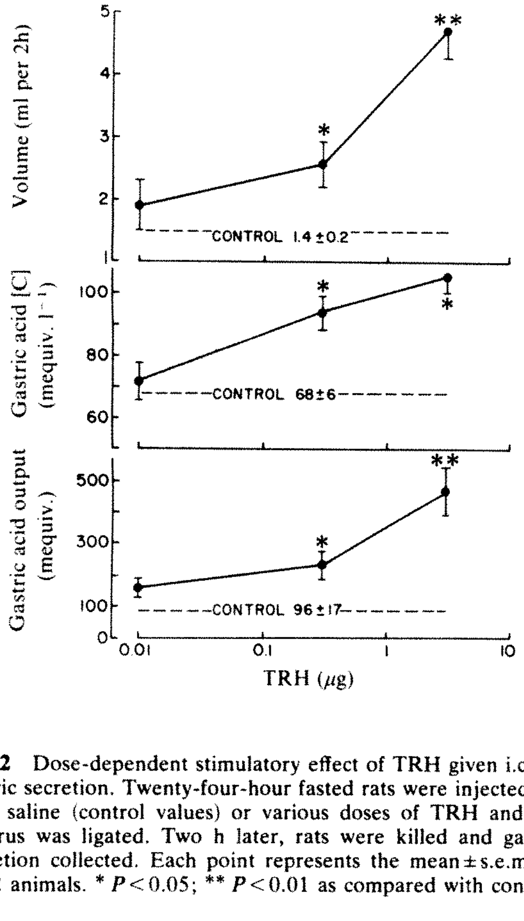

Fig. 2 Dose-dependent stimulatory effect of TRH given i.c. on gastric secretion. Twenty-four-hour fasted rats were injected i.c. with saline (control values) or various doses of TRH and the pylorus was ligated. Two h later, rats were killed and gastric secretion collected. Each point represents the mean±s.e.m. of 5–12 animals. * $P<0.05$; ** $P<0.01$ as compared with control.

1 h, thereafter it returned to the level of control group (Fig. 1). A significant dose-related stimulatory effect is observed following i.c. injection of TRH in doses ranging over 0.3–3 μg as measured 2 h after peptide injection and pylorus ligature (Fig. 2). TRH given i.v. at 10 or 100 μg dose per animal exerted no effect on gastric secretion (data not shown). Using a different experimental design, Morley *et al.* have observed in dogs that TRH inhibited gastric acid secretion stimulated by tetragastrin[17] for the first 15 min. The activity of TRH given i.c. and its ineffectiveness given i.v. strongly support the concept that TRH initially acts through the brain to elicit the stimulation of gastric secretion. The tripeptide has already been shown to have a broad spectrum of CNS-mediated actions unrelated to its neuroendocrine activity, including modification of behavioural[18] and hormonal[19-21] effects of narcotics, or biogenic amines, alteration of thermoregulation[22], blood pressure[23], food intake[24] and muscular activity of gut[12,13]. The stimulatory effect of TRH on gastric secretion appears long-acting, dose-dependent, reversible and specific. The specificity is demonstrated by the inactivity of TRH analogue [^{1}Me-His^2]-TRH (Table 1) which likewise has been found ineffective in other bioassay systems[19,22,25], whereas the active analogue [^{3}Me-His^2]-TRH (ref. 25) mimicked the stimulatory effect of TRH on gastric secretion. Antimuscarinic compounds have been shown to antagonize several CNS-mediated effects of TRH including those on eye pupil[18] and gut muscular activity[12,13]. The effectiveness of vagotomy (data not shown) or atropine (Table 2) in inhibiting the stimulatory effect of TRH on gastric secretion supports the concept that vagus-dependent cholinergic mechanisms could participate in the expression of the gastric response to TRH. However, the exact neuroanatomic site, as well as the CNS and peripheral neuronal/humoral circuits involved, remain to be further identified. On the basis of stimulation and lesion experiments, the hypothalamus (mainly the lateral and ventromedial regions) has been demonstrated in rats to participate in brain control of gastric secretion[26,27]. The fact that high concentrations of TRH are present in the hypothalamus[28] supports the possibility that endogenous TRH may have physiological significance as a CNS chemical messenger involved in brain modulation of gastric secretion.

Evidence that substance P is a neurotransmitter in the myenteric plexus

Kiichiro Morita*, R. Alan North* & Yoshifumi Katayama†

* Neurophysiology Laboratory, Department of Pharmacology, Loyola University Stritch School of Medicine, Maywood, Illinois 60153
† Department of Physiology, Kurume University Medical School, 67 Asahi-machi, Kurume-shi 830, Japan

Substance P (SP) is an undecapeptide originally isolated from the gut[1] and since shown to occur within neurones in several parts of the peripheral[2,3] and central[4] nervous systems. Immunohistochemical studies indicate an exceedingly dense network of SP-containing nerves within the myenteric plexus of the guinea pig ileum[5,6]. These nerves are intrinsic to the gut wall[5,7] and can release SP to contract the longitudinal muscle layer[8,9]. We have previously shown[10,11] that SP directly depolarizes myenteric neurones and that this depolarization has a time course and ionic mechanism similar to the slow excitatory postsynaptic potential (e.p.s.p.) which can be produced by electrical stimulation of presynaptic nerves within the myenteric ganglia. We wondered whether SP might mediate this slow synaptic potential[10]. We report here that the SP depolarization and the slow e.p.s.p. are reversibly depressed by chymotrypsin, an enzyme which degrades SP, although the responses to acetylcholine, serotonin and an unknown hyperpolarizing transmitter are unaffected. The results provide direct evidence that a peptide can mediate chemical transmission between neurones in the mammalian nervous system.

Intracellular recordings were made from neurones in myenteric ganglia which had been dissected from the ilea of adult guinea pigs[12]. These ganglia were perfused *in vitro* with warm (37 °C) Krebs solution to which known concentrations of SP or chymotrypsin could be added. The neurones could be seen using Nomarski optics and this allowed placement of the tips of iontophoresis electrodes containing SP or serotonin close to the soma membrane of the impaled cell[11,12]. Focal stimulation of the ganglion surface evoked fast cholinergic synaptic potentials in one class of cells (type 1 (ref. 12), S cells[13]) and sometimes caused a much slower depolarization[14] in both types of cell (also type 2 (ref. 12), AH cells[13]). Perfusion of SP depolarized both types of myenteric neurones and also reversibly blocked the slow e.p.s.p. and the depolarizing response to SP iontophoresis; it did not block the fast cholinergic e.p.s.p. This finding at least suggested that the perfused SP may desensitize the myenteric neurones to the transmitter released by nerve stimulation.

Perfusion of the preparation with chymotrypsin (200 μg ml^{-1}) reversibly abolished the responses to SP applied by either perfusion (Fig. 1*a*) or iontophoresis (Fig. 2). The response to SP iontophoresis could be restored in the presence of chymotrypsin by increasing the amplitude or duration of the ejecting current, arguing against a destruction or inactivation of postsynaptic sites and in favour of enzymatic degradation of SP between the time of its release from the iontophoresis pipette and its action on the cell membrane. Chymotrypsin (200 μg ml^{-1}) reversibly abolished the slow e.p.s.p. (Fig. 1*b*). When the synaptic potential was depressed by chymotrypsin, it could sometimes be restored by increasing the frequency or duration of the stimulating train of pulses. Chymotrypsin usually did not change the membrane potential, input resistance, action potentials or fast e.p.s.p.; nor did it affect the slow hyperpolarizing synaptic potentials which were occasionally observed in response to nerve stimulation[14]. Higher concentrations of chymotrypsin (300–1,000 μg ml^{-1}) depolarized myenteric neurones, often irreversibly. Chymotrypsin (200 μg ml^{-1}) did not block either the depolarizing or the hyperpolarizing responses to iontophoretic application of serotonin (Fig. 2). Carboxypeptidase (200 μg ml^{-1}), which does not cleave the amidated C terminal of SP (ref. 15), had no effect on membrane potential, the fast e.p.s.p., the slow e.p.s.p. and the

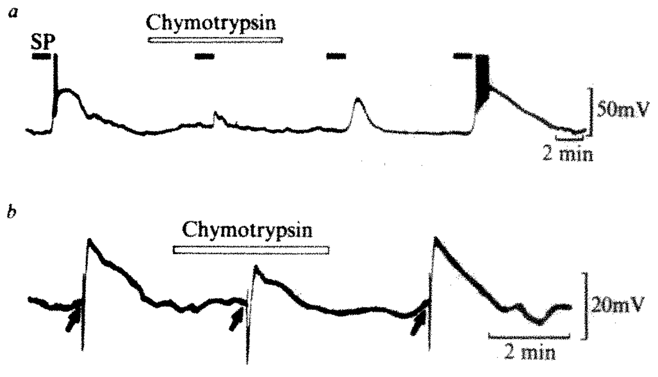

Fig. 1 Recordings of membrane potential from two myenteric neurones. *a*, Substance P depolarization is abolished by chymotrypsin. The perfusion solution contained SP (100 nM) during the four periods (90 s) indicated by the solid bars. The perfusing solution also contained chymotrypsin (200 μg ml^{-1}) where indicated by the open bar. The apparent delay in the onset of the depolarizing action of SP is due entirely to the time taken for the changed solution to flow through the perfusion system before entering the bath (80 s). SP caused a prominent depolarization which initiated action potentials. Chymotrypsin reversibly prevented this action. *b*, Slow e.p.s.p. is depressed by chymotrypsin. The surface of the myenteric ganglion was stimulated with a focal stimulating electrode (10 Hz, 3 s) at the times indicated by the arrows. This caused a short-lasting hyperpolarization followed by a prolonged depolarization (slow e.p.s.p.). Perfusion of chymotrypsin reversibly depressed the slow e.p.s.p. without changing membrane potential or the hyperpolarizing response (which is, presumably, due to a different transmitter).

0028–0836/80/370151—02$01.00

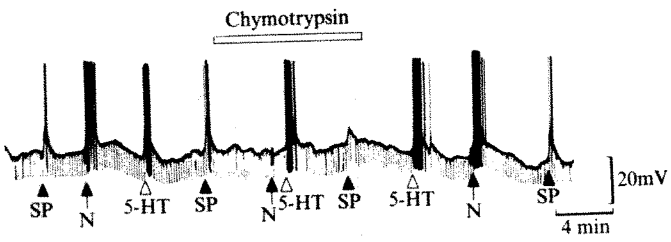

Fig. 2 Membrane potential of a myenteric neurone. Downward deflections are anelectrotonic potentials caused by constant current pulses. SP (100 nA, 5s) and serotonin (5-HT, 20 nA, 10 s) were applied at the times indicated by ▲ and △, respectively. Presynaptic nerves were stimulated (30 Hz, 3 s) at the times indicated by the arrows (N). Both SP and serotonin mimicked the effects of nerve stimulation in this neurone, causing it to depolarize and fire action potentials (full amplitude not recorded). Perfusion with chymotrypsin (200 μg ml^{-1}) did not change membrane potential or resistance but abolished the response to nerve stimulation and greatly reduced the response to SP iontophoresis. The response to serotonin iontophoresis was not depressed.

depolarizing responses to iontophoretic application of either SP or serotonin. Higher concentrations of carboxypeptidase depolarized myenteric neurones, often irreversibly.

In the present experiments, chymotrypsin did not depress the serotonin response in the same cell in which it depressed the slow e.p.s.p. It seems unlikely that serotonin makes a major contribution to the slow e.p.s.p., as has been proposed[16]. It is undetectable in the myenteric plexus of the adult guinea pig ileum without precursor loading and the proportion of cells which contain aromatic amino acid decarboxylase is very low. Furthermore, serotonin either depolarizes or hyperpolarizes myenteric neurones[17], and a substantial proportion of those which are hyperpolarized have ony depolarizing slow e.p.s.ps (Johnson, Y.K., K.M. and R.A.N., in preparation).

The results indicate that a chymotrypsin-sensitive peptide mediates the slow depolarizing potential; the great density of nerve terminals which contain SP make this peptide a likely candidate. At other sites in the mammalian nervous system, evidence for 'peptidergic' transmission remains largely inferential. Enzymatic degradation of released peptide transmitters, although lacking the specificity of pharmacological antagonists, may offer an as yet untested means of establishing the functional role of peptides within the nervous system.

Neurotransmitter turnover in rat striatum is correlated with morphine self-administration

James E. Smith, Conchita Co, Mark E. Freeman, Michael P. Sands & John D. Lane

Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, Louisiana 71130

Drugs of abuse probably exert their reinforcing effects through 'reward' pathways in the central nervous system (CNS)[1,2]. Neuronal systems mediating opiate reinforcement have been investigated using pharmacological and electrolytic lesion procedures. Drugs that interfere with catecholaminergic[3–6] and cholinergic[7] neuronal activity decrease intravenous (i.v.) morphine self-administration in monkeys and rats. Electrolytic lesion procedures in rats have demonstrated that the medial forebrain bundle[8] and caudate nucleus[9] are important in maintaining i.v. morphine self-administration. We have now carried out a direct investigation of striatal (caudate nucleus, putamen and globus pallidus) neuronal systems. We show here that striatal catecholaminergic systems are important in mediating opiate reinforcement, and present direct evidence for the involvement of neurotransmitter systems in morphine reward.

The turnover rates of dopamine (DA), noradrenaline (NA), aspartate (Asp), glutamate (Glu), γ-aminobutyric acid (GABA) and glycine (Gly) were determined in rats self-administering morphine i.v. (condition 1) and in yoked-morphine infused (condition 2) and yoked-vehicle infused (condition 3) littermates. This design was chosen to elucidate the neurochemical effects of the drug alone (conditions 2 and 3) and the effects of the drug self-administration milieu (conditions 1 and 2).

Eleven litters of three (conditions 1–3) adult male Fisher 344 rats were implanted with chronic jugular catheters using a previously described procedure[10,11] and housed together in a large experimental chamber in three separate self-administration cages. Two rats in each litter were made physically dependent over an 8-day period by automatic hourly infusions of morphine in increasing concentrations (2 days each of 1.25, 2.5, 5.0 and 10.0 mg per kg); the third rat received yoked-vehicle (saline) infusions. Each infusion (morphine or saline) was paired with a tone and light stimulus of 30 s duration. Levers were then introduced and one of the physically dependent rats was allowed to self-administer morphine i.v. (10 mg per kg in 0.1 ml saline) by lever pressing. This animal had 24 h access to morphine from that time and could take an infusion on demand by fulfilling the response requirement, which was initially one

Table 1 Content of dopamine, noradrenaline, serotonin (5-HT), aspartate, glutamate, GABA and glycine concurrently measured in the striatum of rats i.v. self-administering morphine and in yoked-morphine and yoked-vehicle infused littermates

	Content						
	pmol per mg protein			nmol per mg protein

Values are means ± s.d. for $n = 11$ in each treatment condition. Student's t-test for differences between means showed no significant changes.

0028-0836/80/370152—03$01.00

lever press. Eventually, 10 lever presses were required for each injection (fixed ratio 10 schedule of reinforcement). The yoked-morphine and yoked-vehicle injected animals in each litter received simultaneous infusions whenever the self-administration animal earned an infusion. Lever presses from these yoked littermates were recorded. However, such responses were infrequent.

After stable baselines of self-administration had been obtained, the cumulative records for the 3 days before death were used to determine an average inter-injection interval for each litter. On the day of pulse-labelling, at 60 ($n = 5$ litters) and 90 min ($n = 6$ litters) before a predicted injection, 0.5 mCi [U-^{3}H]tryptophan (NEN, specific activity 7.1 Ci mmol^{-1}), 1.0 mCi [2,6-^{3}H]tyrosine (Amersham Searle, specific activity 34 Ci mmol^{-1}) and 0.2 mCi D-[U-^{14}C]glucose (ICN, specific activity 210 mCi mmol^{-1}) were injected through the jugular catheter. The three littermates were killed at the calculated injection time by total immersion in liquid nitrogen. The heads were allowed to warm to −20°C, the brain removed, cut into 1-mm coronal sections, and the striata discretely removed from the frozen sections. The striata were individually pulverized in a stainless steel mortar in liquid nitrogen and the content, specific radioactivity and turnover values for DA, NA, Asp, Glu, GABA and Gly were concurrently determined using previously described procedures[12–14].

Stable morphine self-administration usually developed within 3–4 weeks (27 ± 16 days) (all values are mean ± s.d.), the average inter-jection interval being 122 ± 35 min for the 11 self-administering animals. During the pulse-label interval, neither morphine nor vehicle was delivered to the litter even if the self-administering animal responded appropriately for an injection. However, the stimulus light and tone were presented, resulting in conditioned morphine-like stereotypical behaviour (weaving, bobbing, circling) in both morphine-dependent rats in each litter during the pulse-label interval. Self-administering animals responded for an average of 5 ± 4 injections (~50 responses) during the pulse interval, with most responses occurring near the predicted injection time. These non-reinforced lever presses were a small percentage of the total motor activity occurring during the pulse interval so that neurochemical differences between the morphine self-administering rat and the yoked-morphine injected animals would be unlikely to result from the purely motor effects of these non-reinforced lever presses but may well partially result from the motivational effects of non-reinforcement (extinction).

The striatal content of the putative neurotransmitters and amino acids did not differ in any of the treatment conditions (Table 1), whereas turnover rates were very different in the yoked-morphine infused and self-administering animals (Table 2). Passive morphine infusions alone (yoked-morphine group compared with yoked-saline infused group) resulted in an increase in the turnover rates of DA, Glu, Gly and GABA and a decrease in NA utilization. The effects of the contingent administration of morphine were sometimes even greater. Turnover rates of DA, NA, Asp, Glu and GABA were almost twice and Gly almost half as high in the self-administering rats as in the yoked-morphine infused animals.

The differences between the self-administering and yoked-morphine infused animals are important for several reasons. First, these data demonstrate that the contingent effects of drug self-administration behaviour result in changes in the utilization rates of putative neurotransmitters in the striatum that are sometimes greater than the effect of the drug itself. The interaction between the drug and the environmental context of its abuse, as reflected in this study by the conditions of contingent compared with non-contingent administration, is an important factor in abuse potential that has been recognized in the clinical setting. Humans receiving opiates in a passive fashion (for example, hospitalized individuals receiving opiates for pain) are less likely to self-administer the drug after it has been withdrawn or to engage in drug-seeking behaviour than are addicts who self-administer and are subsequently withdrawn. Self-administration sometimes results in greater changes in striatal neurotransmitter turnover than does passive infusion of the drug into yoked littermates, and seems to have marked neurochemical consequences. Second, these differences demonstrate for the first time a neurochemical correlate of drug self-administration behaviour. Our data indicate that the milieu in which a drug is administered cannot be ignored in basic studies of drug action.

Table 2 Turnover rates for dopamine, noradrenaline, aspartate, glutamate, GABA and glycine concurrently measured in the striatum of rats i.v. self-administering morphine and in yoked-morphine and yoked-vehicle infused littermates

	Turnover rates					
	pmol per mg protein per h		nmol per mg protein per h			
	DA	NA	Asp	Glu	GABA	Gly

self-administration	±42.6	±6.3	±5.7	±13.7	±6.6	±0.2
Yoked-morphine	117.8*	10.8*	17.8†	55.7*	12.9*	3.0*
infused	±17.6	±2.2	±2.7	±6.1	±2.5	±0.6
Yoked-vehicle	46.6	45.5	13.9	35.9	3.2	1.5
infused	±7.7	±10.3	±2.8	±3.3	±0.9	±0.3

Turnover rates were measured after administration of ^{3}H-tryptophan, ^{3}H-tyrosine and ^{14}C-glucose. Values are means ± s.d. for $n = 11$ in each treatment group and were calculated as the product of the fractional rate constants (k) and the content values from Table 1. Turnover$_A = k$ (content$_A$). Any measure of neurotransmitter turnover is an approximation, but represents relative rates of metabolism of transmitters and amino acids. Thus, two time points on the linear decay portion of temporal specific activity plots were used to calculate apparent fractional rate constants based on assumptions such as steady state and one open pool, which are obviously not entirely valid and consistent with current concepts of putative neurotransmitter compartmentation. Nevertheless, to obtain a measure of transmitter utilization, the fractional rate constants were calculated as $k = \ln 2/t_{1/2}$, where $\ln 2 = 0.693$ and the $t_{1/2}$ is obtained from a semilogarithmic plot of the specific radioactivities determined at 60 ($n = 5$ litters) and 90 ($n = 6$ litters) min after i.v. injection of 0.5 mCi of ^{3}H-tryptophan, 1.0 mCi ^{3}H-tyrosine and 0.2 mCi ^{14}C-glucose. The turnover rate of serotonin was too low for reliable measurement.

*$P < 0.001$; †$P < 0.01$: the significance of the difference between means as determined with Student's t-test. The self-administration group was compared with the yoked-morphine infused group (effects of self-administration) and the latter was compared with the yoked-vehicle infused group (effects of morphine).

The role of CNS neurotransmitters in opiate action has been extensively investigated[12–19]. Also, several lines of evidence indicate that opiate reinforcement may be mediated by central reward pathways[20–23]. This is further supported by the increase in DA turnover in the striatum of self-administering animals seen in the present study. Furthermore, changes in the turnover rates of the amino acids are consistent with their role as putative transmitters released at a large number of CNS synapses[24]. The interaction of multiple systems during contingent opiate self-administration is now being assessed.

Supraoptic neurones of rat hypothalamus are osmosensitive

W. T. Mason

ARC Institute of Animal Physiology, Babraham,
Cambridge CB2 4AT, UK

It has been found that cells in the region of the supraoptic nucleus (SON) of the hypothalamus are sensitive to osmotic stimuli in a physiological range, and have studied the mechanism by which the osmotic sensitivity arises. An *in vitro* hypothalamic brain slice preparation has been used to make intracellular recordings from the SON. Cells lying in the SON respond to small increases (9–40 mosmol l^{-1}) in the osmolarity of their external environment with a marked increase in firing rate. They respond to NaCl and mannitol although not to glucose. The osmotic sensitivity of SON neurones has a complex origin at both a pre- and a postsynaptic level, being composed first of depolarization of the primary SON neurone by an increase of extracellular osmolarity and second by an increased rate of occurrence of excitatory synaptic events which markedly augment firing rate. These results are consistent with Jewell and Verney's suggestion[1,2] that osmoreception in the mammalian brain occurs in the region of the anterior hypothalamus, and extends this localization by indicating that the SON neurones are themselves both directly osmosensitive and part of an osmoreceptive complex.

Hypothalamic neurones in the mammalian SON are known to control the secretion of oxytocin and vasopressin from the posterior pituitary into the systemic circulation. Jewell and Verney[2] originally proposed that the osmoreceptors regulating vasopressin secretion lay outside the blood–brain barrier in the region of the anterior hypothalamus, and they suggested the SON as one possible site at which osmoreception might occur. Consistent with this, Sladek and Knigge[3] concluded from work with hypothalamo-neurohypophysial explants that the osmoreceptors lay near to the SON. This proposal, however, has generated considerable controversy, centering on three points. First, several workers have disagreed as to whether neurosecretory cells in the SON are themselves osmoreceptors or whether they receive synaptic input from osmoreceptors more distant from the SON[4–6]. Second, is the osmoreceptor really osmotically sensitive, or can the responses observed *in vivo* be accounted for by a sodium receptor[4,5,7–9]? A final area where conflicting results have emerged has been generated by recent work using extracellular recording from the slice preparation by Hatton *et al.*[10] and Wakerley and colleagues[11,12], which found little spontaneous activity and little or no osmosensitivity in the SON, results which conflicted in turn with Leng's finding[6] that direct 'microtap' application of hyperosmolar NaCl *in vivo* excited SON neurones directly. These controversies were thus examined with the potentially powerful *in vitro* slice technique. This technique has several advantages, including: (1) anaesthetics are unnecessary, (2) the preparation is continuously superfused so that known concentrations of substances of interest can be applied, (3) the SON can be identified unambiguously by its proximity to the optic chiasm, (4) the blood–brain barrier is effectively absent, and (5) stable, long-term intracellular records can be obtained.

Coronal or sagittal slices, 300–400 μm thick, of rat hypothalamus were prepared on a vibratome and maintained in oxygenated Yamamoto[14] medium (*p*H 7.5) at 37 °C. The slices were supported on lens tissue/acrylic mesh and O_2/CO_2 (95/5%) moistened with medium blown over them. Perifusion from beneath was accomplished with an LKB peristaltic pump operated at 0.6–1.0 ml min^{-1} in a chamber volume of about 1.5 ml. Renewal of medium in the chamber was 95% complete

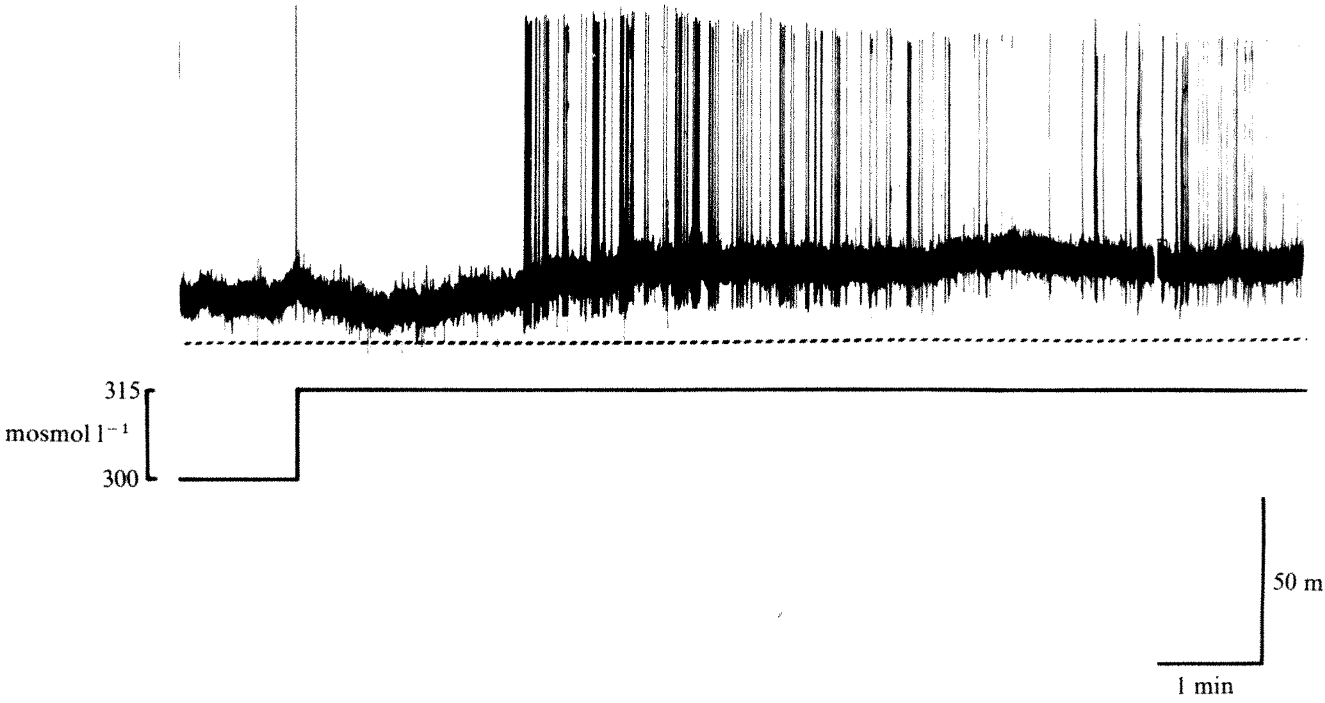

Fig. 1 Intracellularly recorded response from a neurone in the SON of the rat hypothalamus, recorded from a 400-μm slice maintained *in vitro*. Resting membrane potential (V_m) at the start of the record was −61 mV, and membrane resistance (R_m) measured with the bridge balance technique was 140 MΩ. The perifusing medium was changed where indicated to one of higher osmolarity by addition of mannitol, although similar results were obtained with NaCl in other experiments (as in Fig. 2). This cell responded with a clear increase in firing rate, accompanied by a depolarization of V_m of about 12 mV.

0028-0836/80/370154—04$01.00

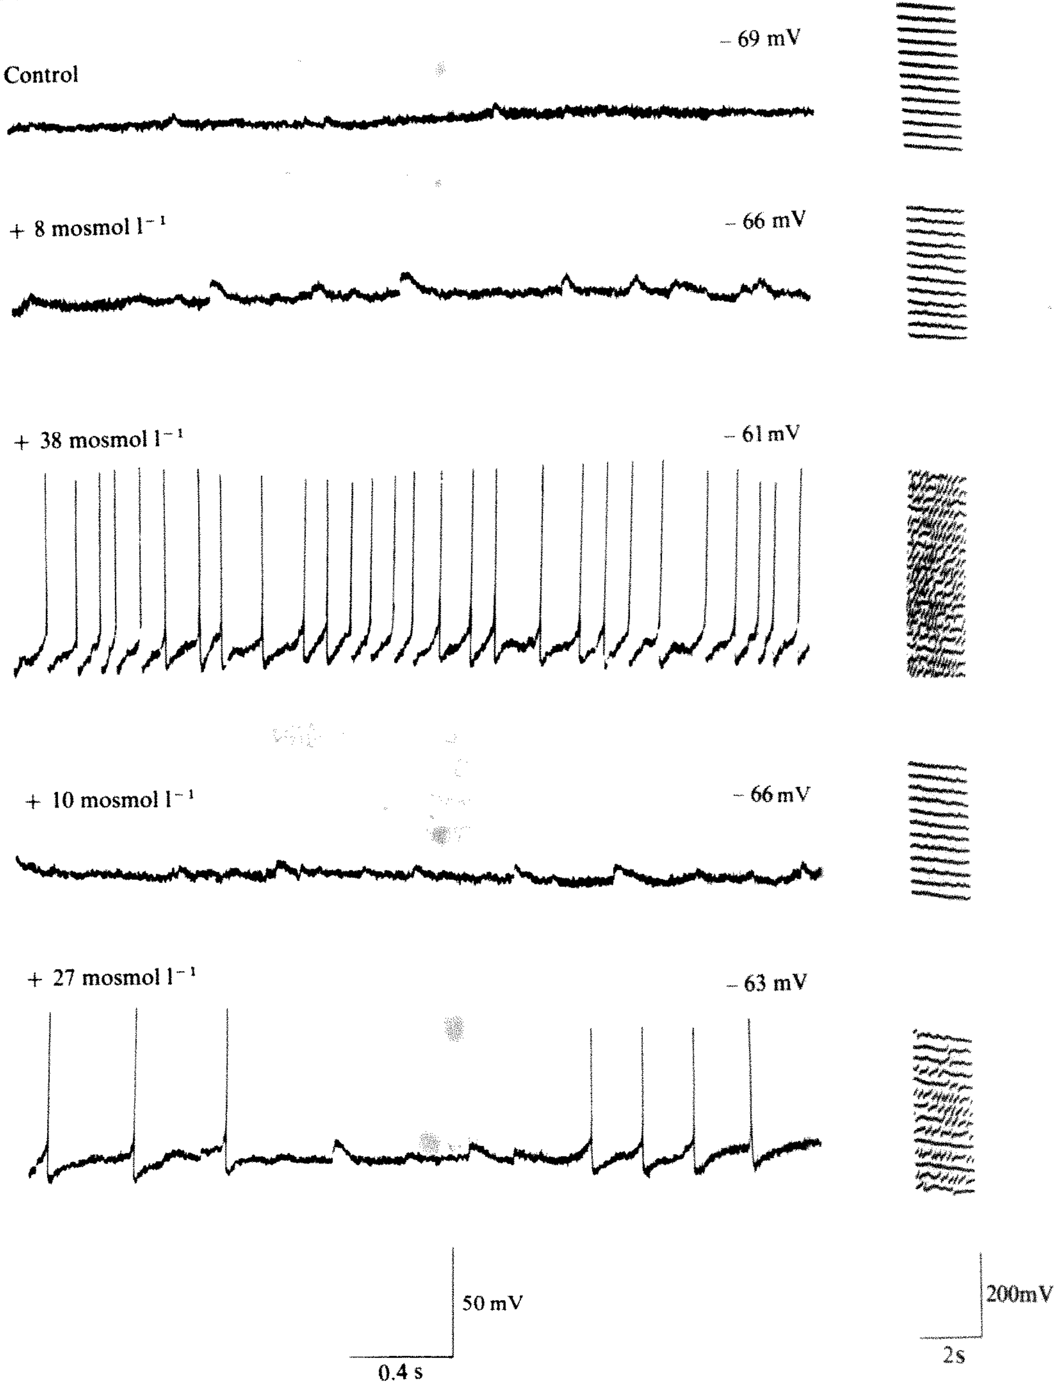

Fig. 2 Osmotic response of a supraoptic neurone recorded intracellularly over a period of 80 min ($R_m \sim 210$ MΩ). In these records, the time scale has been expanded to show the presence of baseline synaptic activity. On the top left of each record is given the presence of baseline synaptic activity. On the top left of each record is given the measured osmolarity change, elicited for this cell by addition of NaCl, with the control value before the start of the osmolarity change being 298 mosmol per kg. The baseline membrane potential for each cell is given on the top right. The records in the main body of the figure were reproduced by a Datalab transient recorder, and spikes have been retouched to represent their accurate height, which had been attenuated by the recorder. Records to the right of the figure are continuous traces photographed from the oscilloscope to show the longer-term baseline spontaneous activity of the same cell, and necessarily, the spike tops in these records have been lost. This cell has been illustrated to show the wide variation in activity which is elicited by osmolarity increase. While this cell would have been classed as a 'quiet' cell due to the lack of cell firing and low frequency of synaptic activity, it is apparent that a small and physiological osmolarity increase modifies both of these properties in a graded manner. Likewise, for a cell exhibiting spontaneous activity when impaled, osmolarity increase amplifies both the frequency of synaptic input and the firing rate of the cell. For this cell, it was possible to effect several changes of the bathing medium, such that a response to osmolarity could be observed, and reversed by returning to the control medium, followed by return to a medium of raised osmolarity about 10 mosmol per kg less than the first test. Resultant spiking was graded with the increase in osmolarity, being 9.2 Hz in the +38 mosmol per kg test and 2.4 Hz in the +28 mosmol per kg test (averaged over 5 min). The response to osmolarity consisted of depolarization of membrane potential, increased firing rate, and an increased frequency of synaptic events. As can be further seen, the initial increase in e.p.s.p. frequency occurred without resultant spiking, action potentials being observed only when V_m allowed the e.p.s.ps to approach threshold, which for this cell was about −50 mV. I.p.s.ps were also observed, although not as frequently as e.p.s.ps in this cell.

in 4–7 min. Osmolarity of the medium was measured with a Knauer semimicro-osmometer. Standard intracellular recording techniques were used, using electrodes filled either with 4M K acetate or 2M Na methylsulphate (resistance 70–250 MΩ). Cells were occasionally marked intracellularly with the fluorescent dye Lucifer CH and examined in wholemount to confirm the recording site as being the supraoptic nucleus.

Some of the basic properties of intracellularly recorded neurones from this preparation have been described previously[13]. SON neurones recorded in slices of hypothalamus showed spike patterning similar to that observed *in vivo*[8,15], and, contrary to earlier reports on hypothalamic slices[10–12], considerable spontaneous activity. In isotonic medium, both phasic and continuous patterns of firing were noted, characteristic of vasopressin- and oxytocin-secreting cells, respectively[8].

When the isotonic perifusion medium (290–295 mosmol per kg) was changed to one of increased osmolarity (305–340 mosmol per kg, with NaCl or mannitol), 19 of 23 cells responded with an overall increase in firing rate (Fig. 1). The increase in spike frequency was superimposed on a slow depolarization of membrane potential (V_m) (13±3 mV (mean±s.d.) for a 35 mosmol per kg increase) graded with osmolarity over a range of 9–45 mosmol per kg. Of the cells responding in this way, three distinct response patterns were observed: (1) 'silent' cells (<0.5 Hz) began to fire (1–10 Hz); (2) slow continuously firing cells (0.5–2.0 Hz) fired more rapidly, firing rate being graded with increase in osmolarity; (3) 'silent' cells and some phasic firing cells began to fire phasically and to fire with an increased burst length, respectively, some eventually firing in a continuous pattern.

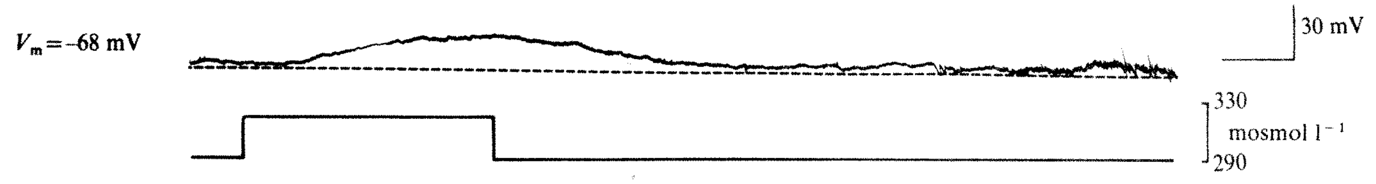

Fig. 3 The effect of increased osmolarity on a supraoptic neurone which had been blocked by increasing the Mg^{2+} content of the bathing medium. R_m was 165 MΩ, measured at the start of the record. Before the beginning of the experiment, after the cell had been impaled, 15 mM $MgSO_4$ was added and an equivalent amount of NaCl removed from the normal medium to maintain the isotonicity at 294 mosmol per kg. This treatment had no discernible effect on V_m. Following this, NaCl was added to raise the osmolarity as shown, and this resulted in a pronounced depolarization of V_m, but without a concomitant increase in firing rate as in Figs 1 and 2. Similarly, as synaptic input to the cell had been largely abolished by Mg^{2+} addition, synaptic potentials were not observed before, during or after increased osmolarity. However, the cell could be driven to fire by intracellular passage of depolarizing current such that V_m was brought above threshold (suprathreshold stimulation for this cell in the presence of Mg^{2+} elicited firing at about 50 Hz). Similar results were obtained where Mg^{2+} was added without removing NaCl, that is, where osmolarity was increased before a test by Mg^{2+} addition. This result indicates that the V_m depolarization resulting from increased osmolarity is a direct action on the primary neurone within the supraoptic nucleus, and not synaptically mediated or requiring synaptic input to the cell.

The firing patterns and depolarization of membrane potential induced by increased osmolarity were completely reversible when cells were restored to isotonic medium. Four 'silent' cells which did not respond to osmotic stimulus with increased firing did, however, depolarize in a manner comparable to responsive cells, but this depolarization did not, at the stimulus used, carry V_m sufficiently close to threshold for activation of firing. Current injected intracellularly through the recording electrode sufficient to depolarize the 'silent' cells beyond threshold elicited rapid firing, as observed in all cells.

During and preceding osmotically induced firing of SON neurones, significant changes in baseline voltage noise were observed. The magnitude of these changes varied from cell to cell and was graded with the measured change in osmolarity. The origin of this noise was a large increase in frequency of synaptic input to the cell, a property previously observed for more peripheral neurones[16–21]. This was analysed to study the correlation between membrane potential, cell firing rate, synaptic events and external osmolarity. Figure 2 shows that increased osmolarity has multiple and synergistic actions on both pre- and postsynaptic properties of SON neurones, in turn leading to an accelerated firing rate. These are increased synaptic input [excitatory postsynaptic potentials (e.p.s.ps) and inhibitory postsynaptic potentials (i.p.s.ps)], depolarization of the postsynaptic cell, and spike generation. For one typical cell, an osmolarity increase of 32 mosmol l^{-1} (w/NaCl) elicited (1) a peak depolarization of 14 mV; (2) increase in frequency of synaptic events (measured postsynaptically) from 3 s^{-1} to 34 s^{-1} (averaged over 5 min) and (3) increase in spike frequency from 1.4 Hz to 6.8 Hz. This observation of increased synaptic input to SON neurones, associated with a change in external osmotic pressure, raised the question of whether osmotically induced depolarization of membrane potential may also have been mediated by slower acting synaptic events, perhaps distant to the SON nucleus.

As demonstrated in Fig. 3, four SON neurones were tested for response to osmolarity increase (three with NaCl, one with mannitol) when they were bathed in 15 mM $MgSO_4$ solutions such that synaptic input was abolished. In three of these experiments $MgSO_4$ was added without removing NaCl and in a fourth experiment $MgSO_4$ replaced NaCl isotonically. The osmotic stimulus was then applied and in all cells a substantial depolarization of V_m resulted, but in the absence of e.p.s.ps/i.p.s.ps and without firing. All cells continued to respond to injected depolarizing current with firing. These results were thus consistent with osmotically induced depolarization being a property of the primary neurone itself rather than a secondary, synaptically mediated event originating either within or outside the SON region.

Finally, the source of the presynaptic input to osmosensitive SON neurones remains a central question as these elements appear to be characterized by osmosensitive properties in their own right. To clarify this question, islands of SON were made from hypothalamic slices previously used for recordings. Not only did nine intracellularly recorded neurones display spontaneous firing and synaptic input as in the intact slice, but also both of two cells tested showed an osmotic response similar to that described above. These observations, coupled with the similarity of response of neurones in coronal and sagittal sections, suggest that both the osmosensitive neurones themselves and the synaptic elements driving these cells lie near to and probably within the SON. The experiments do not of course rule out the possibility that more complex afferent pathways may exist *in vivo*. Inasmuch as the rat SON may not contain interneurones, these results could suggest a functional interaction between excitable SON neurones. In the light of reports that two-thirds of the synaptic input to SON neurones is of intranuclear origin, this might not be surprising[22].

These findings conflict with earlier reports of extracellular recording from hypothalamic slice preparations, in that significant spontaneous activity as well as firing in response to osmolarity changes of the external medium is observed in cells recorded from the SON region. Many features of the spontaneous activity and osmotic responses in these intracellular records closely parallel those observed *in vivo* by means of extracellular recording from anaesthetized animals. These results must therefore strongly support the tentative suggestions of Jewell and Verney[2] as to the siting of the osmoreceptor in the anterior hypothalamus, in confirming that oxytocin- and vasopressin-secreting neurones lying within the SON are part of an excitable osmoreceptive complex. Furthermore, that the osmoreceptive complex as a whole (the pre- and postsynaptic element) lies within or near the SON is indicated by these results, although it cannot be excluded that the osmosensitive presynaptic element is a cut nerve ending of a more distant perikaryon. Whether the basic neuronal properties thus far observed for these osmosensitive cells distinguish them from other central neurones is open to speculation and will require a wide-ranging comparison with cells from other brain regions, but the siting of SON neurones within a dense capillary bed must make them well placed to detect and respond quickly and efficiently to changes in the osmolarity of the blood.

I thank Drs B. A. Cross, R. G. Dyer and G. Leng for helpful discussion and criticism of the manuscript.

Intracellular study of ionic events underlying intestinal membrane transport of oligopeptides

M. R. Ward & C. A. R. Boyd*

Department of Physiology, The University, Dundee DD1 4HN, UK

It is now clear that after a protein meal much of the α-amino nitrogen which is absorbed from the small intestinal tract is transported into the intestinal epithelium across the brush border membrane of the enterocyte in the form of oligopeptides rather than free amino acids[1–3]. We report here the results of electrophysiological experiments using intracellular microelectrodes which allow us to add important information concerning the mechanism of membrane transport which must underlie oligopeptide absorption, in particular with respect to the role of Na^+ in this peptide transport. Such experiments not only reveal the energetics involved in the major pathway for protein absorption from the gastrointestinal tract but may also be important for understanding the mechanism of action of small peptides in quite different cells, such as the Na^+-sensitive binding of the neurohormone oligopeptide enkephalin to the enkephalin receptors in the central nervous system[4,5].

Figure 1 shows the results of a representative experiment in which the potential, V_m, across the brush border membrane of the superfused small intestine of the mudpuppy, *Necturus maculosus*, was recorded by a microelectrode inserted from the mucosal aspect into an epithelial cell[6]. The initial value of $V_m(-45$ mV) is somewhat greater than the mean value we find of 34 ± 2 mV (mean ±s.e.m., $n = 36$), which is almost identical to the mean value found in the same tissue by Garcia-Diaz *et al.*[7]. The cell was exposed initially to the amino acid L-leucine (6 mM), which produced a prompt, marked depolarization of 14 mV which was reversed completely on removal of the amino acid. This confirms previous findings[6,8,9] and strongly suggests an ion-linked co-transport mechanism for entry of this neutral amino acid across the brush border membrane. Subsequent exposure to a higher L-leucine concentration (12 mM) produced a similar reversible depolarization which was almost identical to that found with the lower amino acid concentration, suggesting saturation of the brush border amino acid transport system. The cell was then superfused with a mixture of amino acid (12 mM) and the dipeptide L-leucyl-L-leucine (6 mM). This mixture produced a greater reversible depolarization; also, the rate of depolarization was increased by the presence of the dipeptide in addition to the saturating quantity of monomer. This increase must have been caused by the intact dipeptide rather than the products of extracellular or membrane digestion[10] and therefore shows the existence of a pathway for peptide transport separate from and additional to that for the amino acid. Moreover, it shows that the entry of this neutral dipeptide into the cell via such a pathway is associated with an instantaneous flow of ionic current and thus that peptide transport is electrogenic. Subsequently, the cell was exposed sequentially to 6 mM L-leucine, 12 mM L-leucine and the amino acid and dipeptide mixture (12 mM L-leucine, 6 mM L-leucyl-L-leucine); these solutes were then removed in reverse order. Exposure to the dipeptide produced a prompt 16 mV depolarization of the brush border membrane that was reversed on removal of the solute and was additional to that produced by exposure to a maximal saturating concentration of amino acid.

Ion replacement studies were carried out to elucidate the nature of the current flow induced by the dipeptide, and Fig. 2 shows the result of an experiment in which the effects of the amino acid and of the peptide on V_m were studied in a solution in which Na^+ had been totally replaced by choline. The measured Na^+ concentration in this solution after flow through the bath was 2 ± 1 mM (mean ±s.e.m., 6 observations). In this low concentration of Na^+ the effects on V_m of both amino acid and peptide were not totally abolished; however, the amino acid-induced depolarization was much slower than that seen in the presence of a high external Na^+ concentration (Fig. 1). With the dipeptide there is also a reduction in the rate of depolarization in low compared with high external Na^+, although this reduction is considerably less for the dipeptide than for the amino acid.

These findings may help to resolve the controversy concerning the role of Na^+ in peptide transport. Matthews, Addison and Burston[11] showed that external Na^+ was required for the active accumulation of the poorly hydrolysed dipeptide L-carnosine (β-alanyl-L-histidine) by rings of hamster intestine *in vitro*. Cheeseman and Parsons[12,13], however, found that the trans-epithelial flux of the amino acids glycine and leucine which had entered the tissue as the dipeptides glycyl-L-leucine or L-leucyl-glycine (both of which are hydrolysed intracellularly) was independent of the presence or absence of Na^+ from the intestinal lumen: they suggested that "the non-accumulative entry of the peptides into the epithelium can occur independently of the presence of Na in the lumen". The results shown here clearly demonstrate electrogenic peptide entry for the easily hydrolysed, and therefore non-accumulated, dipeptide L-leucl-L-leucine. The differing sensitivities of the peptide and the amino acid transport systems to a substantial decrease in external Na^+, shown in Fig. 2, is most simply explained on the basis of the driving forces involved, as for any Na^+ co-transport

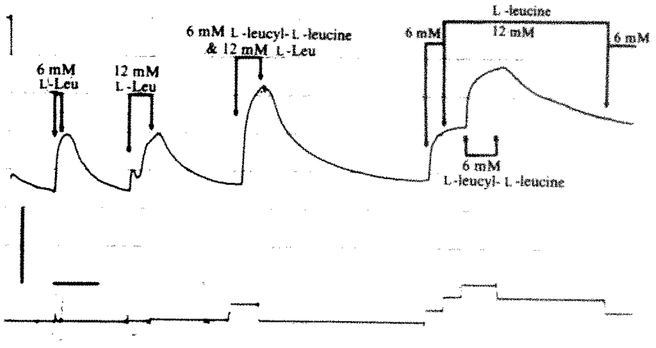

Fig. 1 Pen-recording of the potential across the brush border membrane of an intestinal epithelial cell of the mudpuppy *Necturus maculosus*. A piece of mid-duodenum was superfused at room temperature in a small Perspex chamber (vol. 0.8 ml) at a flow rate of 60 ml min^{-1} with mudpuppy Ringer (Na 115, K 3, Ca 2.7, Cl 116, HCO_3 2.4, PO_4 3.0 mM l^{-1}; pH equilibrated with air, 7.4; osmolarity 220 mosmol l^{-1}). At the start of the trace the cell was impaled from the mucosal aspect under direct visual control with a 24 MΩ glass KCl-filled microelectrode. When a stable recording had been established the composition of the superfusate was abruptly altered as shown (event marker on lower trace). The initial transient observed on exposure to 12 mM L-leucine is due to a small pulse of 6 mM H6W7L-leucine preceding the higher concentration of amino acid. Vertical calibration 20 mV; horizontal calibration 60 s.

---

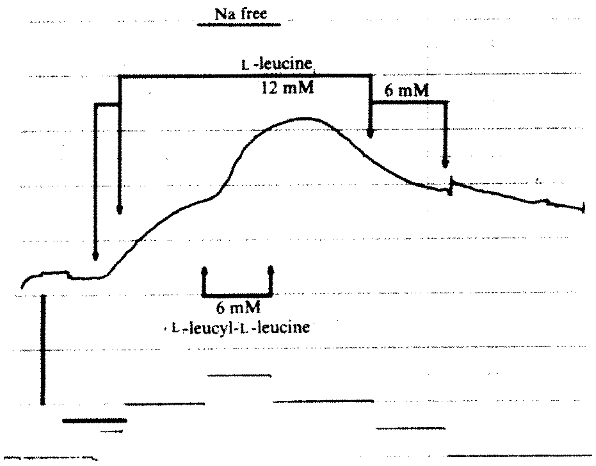

Fig. 2 Pen-recording of the brush border membrane potential of a small intestinal epithelial cell (see Fig. 1). The superfusate was identical to that used in Fig. 1 (except that Na^+ was totally replaced by choline) and its composition was altered as indicated (event marker on lower trace). Initial membrane potential was −47 mV. Vertical calibration, 20 mV; horizontal calibration, 60 s.

system the equilibrium potential[14] is given by

$$V_{\mathrm{equil.}} = \frac{RT}{F} \ln \frac{[\mathrm{Na}^+]_o\,[\mathrm{X}]_o}{[\mathrm{Na}^+]_i\,[\mathrm{X}]_i}$$

where $V_{\mathrm{equil.}}$ is the reversal (equilibrium potential) for that co-transport and $[\mathrm{Na}^+]_o$, $[\mathrm{Na}^+]_i$, $[\mathrm{X}]_o$ and $[\mathrm{X}]_i$ are, respectively, the external and internal Na^+ and co-transported solute activities, and R, T and F have their usual meaning. Clearly, the magnitude of the depolarization observed on exposure to solute will be a function of both the driving force ($V_m - V_{\mathrm{equil.}}$) and the passive membrane resistance[15]. For a readily hydrolysed peptide such as L-leucyl-L-leucine, the intracellular dipeptide activity is kept low because of intracellular peptidase activity; hence, the driving force for Na^+–peptide co-transport will remain high even in solutions with low external Na^+ activity, and peptide transfer coupled to a flow of Na^+ will still occur at an appreciable rate. For both amino acids and poorly hydrolysed peptides in low external Na^+, the driving force will be much reduced because of the intracellular activity of the co-transported substrate, and their uptake will therefore be strongly inhibited.

These experiments show the value of intracellular microelectrode studies in defining the properties and mechanisms of a peptide transport system. By extending the approach to larger oligopeptides it should be possible to classify and map electrophysiologically the peptide transport systems of the brush border membrane. Moreover, the electrogenic nature of peptide transport revealed by such studies may be important with respect to both the evolution[16] and role of small peptides as neurotransmitter and neurohormones in other tissues.

We thank the Wellcome Trust for financial support.

Requirement of nerve growth factor for development of substance P-containing sensory neurones

Uwe Otten*, Michel Goedert*, Norbert Mayer† & Fred Lembeck†

* Department of Pharmacology, Biocentre of the University, CH-4056 Basel, Switzerland
† Institute for Experimental and Clinical Pharmacology, University of Graz, A-8010 Graz, Austria

The protein nerve growth factor (NGF) is known to be essential for the maturation and maintenance of adrenergic neurones[1] and for the development of sensory neurones during critical stages of embryonic life[2–4]. The investigation of the physiological importance of NGF for the development of sensory neurones has been hampered so far by the lack of biochemical marker substances for these neurones. The demonstration that the undecapeptide substance P(SP) is present in sensory neurones[5,6] suggests that it might be such a marker. SP is synthesized in dorsal root ganglia (DRG)[7] and transported to the terminals of C-fibres located in the dorsal horn of the spinal cord and in the skin[8]. Its release can be demonstrated from the central[9,10] and peripheral endings[11] of sensory nerve fibres which seem to have an important role in pain perception[12,13]. We have investigated the effects of NGF and of purified anti-NGF antibodies on the content of SP in rat DRG and in their respective target organs, namely the spinal cord and the skin. The effects on sympathetic ganglia were included in order to control the effectiveness of both NGF and its antibody. We report here that NGF leads to an increase in SP in spinal ganglia, as previously shown by Kessler and Black[14]. However, in contrast to these authors, we describe that the administration of anti-NGF antibodies produces a marked reduction of the SP content in sensory neurones and in their respective nerve terminals.

2.5S NGF was prepared from submaxillary glands of adult male mice according to Bocchini and Angeletti[15]. Antibodies against 2.5S NGF were raised in goats and purified by affinity chromatography according to Stöckel *et al.*[16]. Two-day old Sprague–Dawley rats received subcutaneous (s.c.) injections of NGF (1 μg per g) during three consecutive days or a single s.c. injection of (50 μg per g) anti-NGF antibodies. Tyrosine hydroxylase (TH) activity was determined according to Mueller *et al.*[17]. Spinal ganglia (ThlO-12), corresponding regions of spinal cord and pieces of skin from the hindlimb were prepared and homogenized in ice-cold 2 M acetic acid (2 ml). The samples were centrifuged, washed twice and the combined supernatants freeze dried. SP immunoreactivity was measured by a radioimmunoassay at a detection level of 6 pg SP according to Mroz *et al.*[18]. Protein concentrations were determined according to Lowry *et al.*[19].

Repeated injections of NGF led to an increase in SP in rat spinal ganglia from 131 ± 20 to 200 ± 14 pg SP per ganglion (Fig. 1). The administration of anti-NGF antibodies caused a gradual decrease in SP up to 17 days, the longest time point studied (Fig. 1). This reduction was paralleled by a decrease in SP content of both the spinal cord and the skin (Table 1). The protein content of the spinal ganglia rose from 17 μg per ganglion at two days of age to 44 μg per ganglion at 19 days. Neither NGF nor its antibody had any significant influence on the protein content of DRG. The total TH activity in the superior cervical ganglion (SCG) showed a threefold increase after repeated administration of NGF, whereas the injection of anti-NGF antibodies produced an almost complete disappearance of TH activity (Table 2), thus indicating optimal effects of NGF[22] and of its antibody[23] on sympathetic ganglia.

The present experiments confirm that postnatal sensory ganglia are responsive to NGF and indicate that they require NGF or a cross-reacting NGF-like protein for their normal development, as evidenced by a decrease in their SP content after the administration of anti-NGF antibodies. Thus the concept that sensory neurones are dependent on NGF only during certain stages of their embryonic development[2] must be extended to the postnatal maturation of these neurones. Postnatal dependence may indicate a physiological function for the retrograde axonal transport of NGF found in sensory neurones[24,25]. Future *in vivo* studies will have to show whether the modulation of SP by NGF is restricted only to defined stages of neuronal development. Our findings do not rule out the possibility that the reduction in SP effected by anti-NGF antibodies is due to neuronal death rather than to an impaired function of sensory neurones. The lack of a decrease in total protein content would, however, suggest that the anti-NGF antibodies only interfere with the functioning of DRG. Future studies will also have to investigate whether other neuropeptides found in sensory ganglia, like somatostatin and cholecystokinin[26], are affected by both NGF and its antibody. Previous studies have shown an effect of NGF on the SP content of DRG in explant cultures[27,28]. Kessler and Black[14] described a significant effect of NGF on the postnatal development of rat sensory neurones, while failing to find an effect of NGF antiserum. The discrepancy between these results and our findings may well be explained by the fact that the antiserum used was less potent than our purified anti-NGF antibodies, as evidenced by the decrease in TH activity in the SCG.

In conclusion, the present results indicate that NGF or a cross-reacting NGF-like molecule is important for the postnatal development of SP-containing sensory neurones. They also suggest that, in addition to the drug capsaicin[29,30], anti-NGF antibodies might be a tool for reducing the SP content of primary sensory neurones.

We thank Mrs M. Burnett for technical assistance and Ms R. Schuligoi for performing the radioimmunoassays. Part of this work was supported by the Austrian Scientific Research Fund (Grant 3506 and 3400).

Table 1 Effects of anti-NGF antibodies on SP content of spinal cord and skin

Spinal cord	
Controls	206 ± 6
Anti-NGF antibodies	126 ± 13*
Skin	
Controls	28 ± 3
Anti-NGF antibodies	15 ± 2*

Two-day old rats were injected with 50 μg g^{-1} anti-NGF antibodies. They were killed 17 d later and SP content (ng per g of tissue) determined. Each value represents the mean ± s.e.m. ($n = 5$ animals).

$*P < 0.01$.

Table 2 Effects of NGF and anti-NGF antibodies (NGF-AB) on TH activity in the rat superior cervical ganglion (SCG)

	Controls	Treated
NGF	134 ± 12.4	388 ± 62.8*
NGF-AB 3 d after injection	122 ± 14.2	32 ± 1.3*
NGF-AB 7 d after injection	178 ± 14.2	21 ± 0.6*
NGF-AB 17 d after injection	242 ± 18.2	11 ± 0.2*

Two-day old animals were treated with either 1 μg g^{-1} NGF or 50 μg g^{-1} anti-NGF antibodies. NGF was injected on three consecutive days and the animals killed one day after the last injection. Anti-NGF antibodies were injected once and the animals killed 3, 7 and 17 d later. The SCGs were rapidly removed and homogenized in 5 mM Tris-HCl buffer, pH 7.4 (0.5 ml), containing 0.1% Triton X-100. TH activity was determined according to Mueller *et al.*[17]. Each value represents the mean ± s.e.m. ($n = 4$–6 animals). Results are expressed as pmol dopa per h per pair ganglia.

$*P < 0.005$.

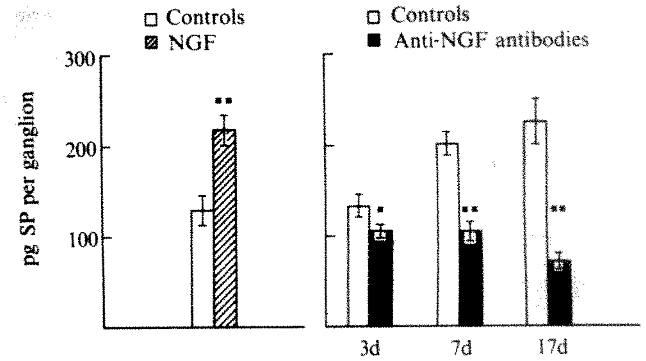

Fig. 1 Effects of NGF and anti-NGF antibodies on content of SP in rat DRG. Two-day old rats were injected s.c. with either 1 μg g^{-1} NGF or 50 μg g^{-1} anti-NGF antibodies. 2.5S NGF was prepared according to Bocchini and Angeletti[15], with the modifications described by Suda *et al.*[20]. The biological activity of NGF was determined according to Fenton[21] and it amounted to 250 biological units per μg of protein. Antibodies against 2.5S NGF were raised in goats and purified by affinity chromatography[16]. Injection of NGF was performed on three consecutive days and SP content in DRG was examined one day after the last injection. Anti-NGF antibodies were injected once. Animals were killed 3, 7 and 17 d after injection and the DRG examined for SP content. Each value represents the mean ± s.e.m. ($n = 4$–6 animals). $*P < 0.01$; $**P < 0.005$.

Tranquillizers can block mitogenesis in 3T3 cells and induce differentiation in Friend cells

G. D. Clarke & P. J. Ryan

Cell Proliferation Laboratory, Imperial Cancer Research Fund,
PO Box 123, Lincoln's Inn Fields, London WC2A 3PX, UK

Compounds of diverse structure induce murine Friend erythroleukaemia (MEL) cell[1] differentiation[2–5]. Seeking a common property[6], Bernstein[7] reported that the relationship between activity and octanol/water partition coefficients for inducers resembled that reported for anaesthetics[7]; moreover, anaesthetics inhibited induction. Since anaesthetics were known to increase membrane fluidity, they suggested that inducers might decrease it. Reporting evidence against unitary theories of anaesthesia[9], Richards *et al.*[10,11] suggested that lipophilic drugs competed, according to their individual structure, with membrane lipids for hydrophobic regions on membrane proteins. The antagonism between pairs of anaesthetics[10,11], anaesthetics and inducers[7,8] and pairs of inducers[5], might thus be explained economically by Richards' anaesthesia model, inducers and lipophilic drugs acting by similar rather than contrary mechanisms. Lipophilic drugs should, therefore, induce differentiation. We report here that some tranquillizers do so. As reported elsewhere for classical inducers[12], they also block non-differentiating 3T3 cells in pre-S. These findings may have application in cancer chemotherapy.

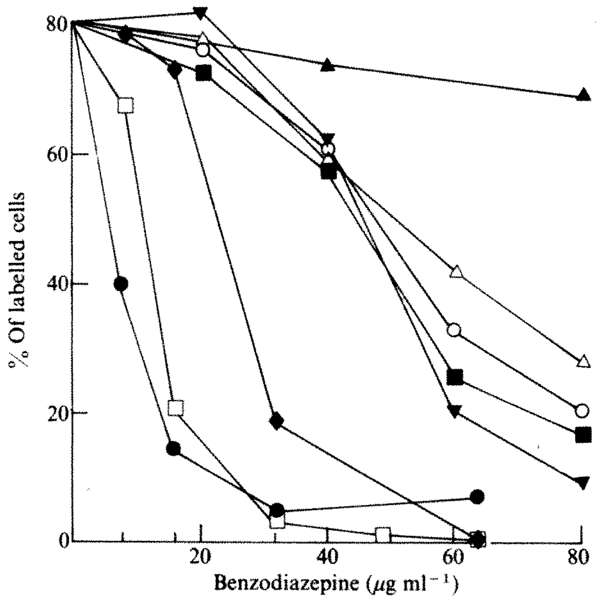

Fig. 2 Swiss 3T3 (4A recloned[27]) cells were maintained in Dulbecco Eagle's medium containing 10% calf serum. Cultures with 2.5×10^4 cells in 2 ml of medium containing 0.5% serum were incubated in 3 cm plastic Petri dishes (Nunc) for 3 days at 37 °C. Medium was then replaced with 6% serum medium containing 30 μM inosine, 2 μC ml^{-1} of tritiated thymidine (Radiochemical Centre, 21 Ci mmol^{-1}) and indicated concentrations of benzodiazepines: ■, chlordiazepoxide from 20 mg ml^{-1} in normal saline; ●, diazepam; ○, flurazepam; ◆, lorazepam; □, medazepam; △, nitrazepam; ▼, oxazepam; and ▲, temazepam, each from 100 mg ml^{-1} solutions in dimethyl sulphoxide. After 26 h incubation, cultures were fixed in formol saline and prepared for autoradiography[16]. The percentage of labelled cells was calculated from differential counts of 300 cells each on duplicate dishes. Cultures with 0.02–0.08% dimethyl sulphoxide did not differ from controls.

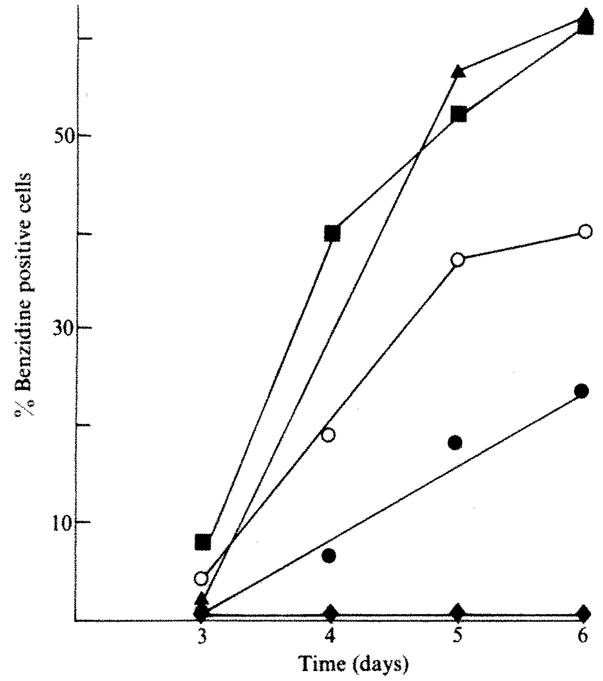

Fig. 1 MEL cells were seeded (as in Table 1 legend) at 3×10^4 ml^{-1} at 0 (◆), 8 (●), 16 (○) and 32 μg ml^{-1} (■) diazepam (dissolved directly into media) and 2.5% dimethyl sulphoxide (▲). Cultures were incubated at 37 °C and duplicates removed daily and stained (Table 1 legend).

The benzodiazepines are a group of tranquillizers which induce anaesthesia in man on intravenous injection[13], yet produce few toxic symptoms when high doses are administered orally or intraperitoneally to mice. We incubated MEL cells for 5 days with concentrations of eight benzodiazepines and stained with benzidine reagent[14] to determine the proportion of the cell population which had accumulated haemoglobin (B+ benzidine positive). At up to lethal concentrations, three of the drugs induced differentiation (Table 1). Diazepam (Valium) and temazepam (Euhypnos) were highly active, giving rise to >50% B+ cells at 40 μg ml^{-1}. Figure 1 shows a time course indicating that 32 μg ml^{-1} of diazepam was as active as 2.5% dimethyl sulphoxide.

We report elsewhere[12] that a wide range of known inducers (dimethyl sulphoxide, hexamethylene bisacetamide, butyrate, ouabain and hypoxanthine) also inhibit the mitogenic effects of serum on 3T3 cells at inducing concentrations. Moreover, volatile anaesthetics such as halothane and nitrous oxide are known to inhibit cell proliferation[15]. We therefore tested the eight benzodiazepines for similar activity.

When 3T3 cells are incubated in medium with 0.5% serum they become quiescent with a low thymidine labelling index[16]. Incubation in medium with 6% serum for 26 h raised this index to 88% and this was reduced to below 35% by 16–80 μg ml^{-1} of seven of the benzodiazepines (Fig. 2). Diazepam was the most active but temazepam, an active inducer at 10 μg ml^{-1}, had little inhibitory effect at 80 μg ml^{-1}. The reduction in the 26-h labelling index was not the result of a brief delay in entry into S phase. In a 5-day growth experiment (Fig. 3), control cultures increased 18-fold but no proliferation occurred in diazepam (64 μg ml^{-1}). Time lapse cinematography showed that only 15% of cells

0028-0836/80/370160—02$01.00

Table 1 Percentage of benzidine positive (B^+) cells induced by benzodiazepines in MEL cell population

Drug	Drug concentration (μg ml^{-1}) 10	20	40	80

Temazepam	24.1	ND	54.2	ND
None	2.7			

Cells of MEL subline F4[26] were maintained in equal parts of Dulbecco Eagle's and Hams F12 medium containing 7.5% fetal calf and 5% calf serum. Duplicate 1-ml volumes of medium, with no addition or with benzodiazepines, were seeded with 3×10^4 cells each in multidishes (Linbro). Chlordiazepoxide was dissolved initially to 20 mg ml^{-1} in normal saline, the other drugs to 100 mg ml^{-1} in dimethyl sulphoxide. After incubation at 37 °C for 5 days, 200-μl aliquots were stained with benzidine reagent[14] and the percentage B^+ (blue) calculated from counts in a haemocytometer. Cultures with dimethyl sulphoxide at 0.02–0.08% did not differ from controls. Diazepam and temazepam dissolved directly into medium were equally active. D, Dead; ND, not determined.

divided and 10% died. When cells were changed to control medium after 48 h in diazepam, 99% divided in 31 h and an 18-fold increase occurred in 5 days (Fig. 3). Thus, diazepam is cytostatic rather than cytotoxic at this concentration.

Induction of differentiation by two tranquillizers supports the view that lipophilic drugs and inducers are a single group, active by virtue of membrane solubility. Our finding that five known inducers[12] and now diazepam, inhibit 3T3 cells at concentrations at which they induce differentiation in Friend cells, is compatible with a hypothetical inverse relationship between the probabilities of proliferation[17] and terminal differentiation[18,19]. This relationship is also suggested by the differentiation in medium with reduced growth potential of normal muscle[19] and adipose[20] cells. We have recently found that 5 of 16 further benzodiazepine derivatives tested induce differentiation in Friend cells. There is no correlation between this activity of the total of seven such inducers and their reported degree of inhibition of ^{3}H-diazepam binding to rat brain membranes[28].

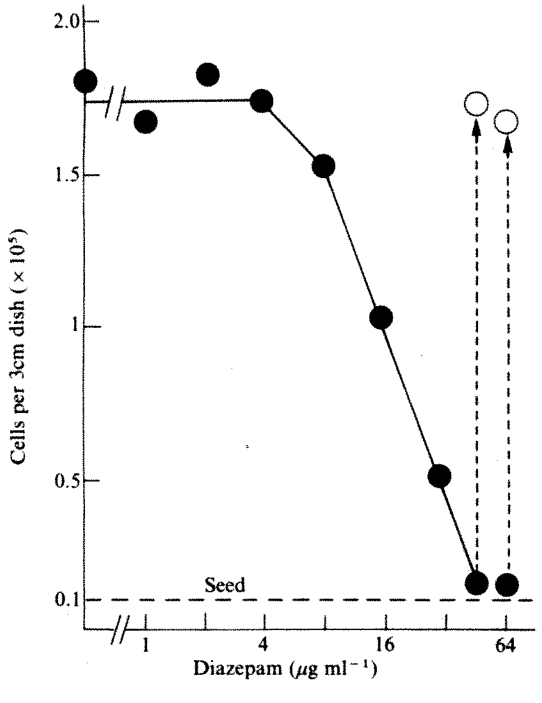

Fig. 3 Control cultures and those containing indicated concentrations of diazepam dissolved directly in 2 ml volumes of medium (Fig. 2 legend) containing 10^4 cells in 3-cm Petri dishes were incubated at 37 °C for 5 days (●). Mean cell counts on duplicated dishes were made with an electronic Coulter counter. Duplicate cultures containing 48 and 64 μg ml^{-1} of diazepam were incubated for 48 h and medium then replaced with drug-free medium for a further 5 days incubation (○) before cell counts.

These findings may have applications in cancer chemotherapy. Agents which hold normal, but not malignant, cells in pre-S have been shown *in vitro* to protect them preferentially against S phase-specific anticancer drugs[21–23]. Benign lipophilic drugs like Valium could conceivably do so *in vivo* (Fig. 3), thus increasing the therapeutic index of such drugs as antifolates, cytosine arabinoside, hydroxyurea and vinca alkaloids. They might also increase differentiation in tumours (see Table 1). Preisler *et al.*[24] have reported that an inducer of Friend cell differentiation may, in some situations, reduce tumour growth rate in mice. Many existing anticancer drugs are lipophilic and it seems possible that their action may not entirely conform with the antimetabolic roles for which they were originally tested. Screening of lipophilic CNS drugs used in man in tumour-bearing mice alone and as protective agents with other anticancer drugs could be worthwhile.

Gifts of drugs, diazepam, chlordiazepoxide, flurazepam, nitrazepam amd medazepam (Roche), lorazepam and oxazepam (Wyeth), and temazepam (Montedison) are acknowledged. Dr Peter Riddle carried out the microcinematography and its analysis and Phil Whitehead assisted in some experiments. We thank Drs Robert Bürk and Ugo Rovigatti for helpful advice and discussion.

Note added in proof: A recent paper by Fehér and Gidali[30] describes the protective effect, for cycling cells of bone marrow against hydroxyurea, of actinomycin D, a lipophilic inducer of Friend cell differentiation[30]. This paper has also drawn our attention to earlier reports of similar specific blocking of normal cell *in vivo* by halothane and nitrous oxide[31–33].

Thymic lymphocytes bear a surface antigen which cross-reacts with acetylcholine receptor

Sara Fuchs, Ilana Schmidt-Hopfeld, Giuseppe Tridente & Rebeca Tarrab-Hazdai

Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Acetylcholine receptor (AChR) is a major antigen in the neuromuscular disease myasthenia gravis and it is clear today that the basic defect in this disease is brought about by an autoimmune attack on acetylcholine receptors at the neuromuscular junctions[1,2]. The involvement of the thymus and its role in myasthenia have been widely investigated but are still poorly understood. A high incidence of thymic abnormalities is observed in patients with myasthenia[3] and thymectomy is beneficial in many cases[4]. Immunological studies have demonstrated the presence of humoral as well as cellular immune responses towards thymic tissues in myasthenic patients[5-7]. There were also some reports that animals immunized with thymic extracts develop a partial defect in neuromuscular transmission[8]. In spite of all these observations, the nature and origin of the association between the thymus and the neuromuscular junction in myasthenia gravis are still not known. We have previously demonstrated an immunological cross-reactivity, both humoral and cellular, between a thymic component and AChR[9]; such a cross-reactivity could provide a molecular explanation for the involvement of the thymus in myasthenia gravis. In this study, we demonstrate, by using immunofluorescence and radioimmunological techniques, that thymic lymphocytes bear a surface antigen which binds specifically to antibodies against nicotinic AChR and is thus defined as an 'AChR-like' antigen. A preliminary report of this study has been published[10].

Thymuses from normal mice (C57BL/6 or SJL, 5–7 weeks old) were dispersed to cell suspensions in a phosphate-buffered saline containing 2% bovine serum albumin and 0.02% sodium azide (diluent). The cells were washed, centrifuges for 7 min at 1,200 r.p.m. and resuspended to a concentration of 10^7–10^8 cells ml^{-1}. Anti-AChR sera were obtained in various animal species by immunization with *Torpedo californica* purified AChR[2,11]. For the immunofluorescence studies, 100 μl of the tested antiserum, immunoglobulin or purified antibodies were incubated for 30 min in the cold with 100 μl of thymic cell suspension (10^6–10^7 cells in the diluent) and the mixtures were centrifuged to remove the unbound proteins. The cells were washed twice and then reacted for an additional 30 min at 4 °C in the dark with the appropriate fluorescent reagent. The labelled washed cells were observed in the fluorescence microsope or were analysed in the fluorescence activated cell sorter (FACS)[12]. For the radioimmunological measurements, the binding of anti-AChR antibodies to thymocytes was quantified by ^{125}I-protein A (Table 1)[13].

As depicted in Fig. 1, thymocytes of normal C57BL/6 mice were specifically labelled by treatment with anti-*Torpedo* AChR immunoglobulins, followed by fluorescein- or rhodamine-conjugated goat anti-rabbit immunoglobulins. A large number of the reacted thymocytes (at least 80%) were fluorescently labelled (Fig. 1*a*, *d*). The fluorescence was evenly distributed on the cell surface in minute patches (Fig. 1*a*). Capping of the patches was observed following removal of sodium azide and further incubation at 37 °C (Fig. 1*b*). Immunoglobulins or serum from normal rabbit or anti-ovalbumin immunoglobulins did not result in any staining (Fig. 1*c*, *f*).

The microscopic findings were verified by quantitative analysis of the same samples in the FACS. Specific fluoresence peaks were obtained following labelling with anti-AChR serum, immunoglobulins or purified antibodies (Figs 2 and 3). The labelled cells were shown to be the size of lymphocytes according to their light scattering. Increasing the amounts of the specific rabbit immunoglobulins added resulted in a shift of the peak towards higher relative fluorescence intensity (Fig. 2). It should be noted that C57BL/6 thymocytes were fluorescently labelled also with anti-*Torpedo* AChR sera prepared in monkey or even C57BL/6 mice (Fig. 3*a*, *b*). The reaction with mouse (C57BL/6) anti-AChR serum was of lower intensity than those obtained with rabbit or monkey sera and could be detected only in the higher sensitivity of the FACS (660 V, Fig. 3*b*). Specific binding of anti-AChR sera or immunoglobulins to mouse thymocytes was also observed by radioimmunoassay measurements (Table 1).

Several experiments were performed in order to verify the specificity of the binding to thymocytes. Thus, it was shown that purified anti-AChR antibodies (purified on an AChR-Sepharose adsorbent) bound specifically to thymocytes (Fig. 3*c*, Table 1). Absorption of anti-AChR antibodies on an AChR-Sepharose adsorbent[14] abolished the ability to bind to thymocytes. These two experiments provide direct proof that the reacting antibodies are indeed anti-AChR antibodies and rule out the possibility that antibodies of other non-AChR specificities which could be present in the immunized animals, due to additional autoimmune responses, could react with the thymocytes. Moreover, immunoglobulins or purified antibodies from non-myasthenic rabbits immunized with denatured AChR

Table 1 Binding of anti-AChR to mouse thymocytes

Thymocytes	Sample	Binding (c.p.m.) (dilution)		
	Sera	1/2	1/4	
C57BL/6	Rabbit anti-AChR	46,420	37,310	
	Rabbit anti-RCM-AChR	49,140	47,420	
	Rabbit anti-(T, G)-A-L	16,250	10,200	
	Rabbit normal serum	20,100	N.D.	
C57BL/6	Monkey anti-AChR	75,210	68,420	
	Monkey normal serum	20,210	19,460	
C57BL/6	Mouse (C57BL/6) anti-AChR	46,320	22,470	
	Mouse (C57BL/6) normal serum	19,200	9,720	
			(μg)	
	Immunoglobulins	750	375	180
C57BL/6	Rabbit anti-AChR	51,250	35,720	12,910
	Rabbit anti-ovalbumin	7,870	9,000	8,840
			(μg)	
	Purified antibodies	24	18	
C57BL/6	Rabbit anti-AChR	10,510	4,950	
	Rabbit anti-RCM-AChR	N.D.	4,610	
	Rabbit anti-ovalbumin	1,950	40	
SJL	Rabbit anti-AChR	8,720	2,920	
	Rabbit anti-ovalbumin	1,130	230	

Thymocytes (10^5–10^6 suspended in 50 μl of diluent) were added to aliquots, (100 μl) of the tested sera or immunoglobulins, in wells of microtitre plates. Following an incubation at 4 °C for 30 min, the plates were centrifuged and washed twice with the diluent. ^{125}I-protein A[13] was added (100 μl per well, approximately 150,000 c.p.m.) and the plates were incubated in the cold for an additional 60 min. The plates were centrifuged and washed twice and the wells were separated and counted. Each dilution or immunoglobulin sample was assayed in triplicate and the amount of binding was determined after subtraction of the background radioactivity obtained by incubation of the thymocytes with the diluent instead of the tested serum or immunoglobulin. The background values were about 3,500 c.p.m. and 1,000 c.p.m., respectively, for the two different preoparations of ^{125}I-protein A used for these experiments. The first preparation was utilized in the experiments with sera and immunoglobulins and the second one in the experiments with purified antibodies.

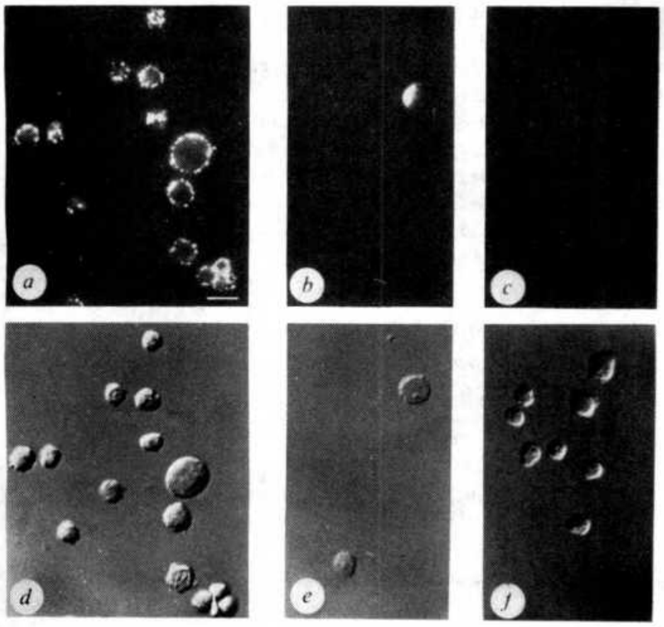

Fig. 1 Immunofluorescent staining of C57BL/6 thymocytes with anti-AChR antibodies. *a*, *b*, Epifluorescence of cells incubated with rabbit anti-AChR IgG followed by rhodamine-goat anti-rabbit IgG. *d*, *e*, Same fields photographed with Nomarski optics. Cells were incubated at 4 °C in the presence of 10 mM NaN_3 (*a*, *d*) and at 37 °C in the absence of azide (*b*, *c*). *c*, *f*, Control: cells were incubated with rabbit anti-ovalbumin IgG instead of anti-AChR. Other conditions are as in *a*, *d*, respectively. Scale bar, 10 μm.

preparation (reduced carboxymethylated AChR, or RCM-AChR[15]) also bound to thymocytes (Fig. 3*d*, Table 1).

In all the experiments described so far, thymocytes from C57BL/6 mice were tested. This mouse strain was shown to be susceptible to experimental autoimmune myasthenia gravis (EAMG)[16]. Similar experiments were performed with thymocytes from a non-susceptible strain[16] in order to test whether the non-susceptibility to EAMG in the latter mice could result from the absence of the 'AChR-like' antigen on their thymocytes. Experiments performed with thymocytes of SJL mice also demonstrated a specific binding of rabbit and monkey anti-AChR sera and of rabbit anti-AChR purified antibodies (Table 1), similar in intensity to that obtained with C57BL/6 thymocytes. These results indicate that the non-susceptibility of SJL mice to EAMG is not associated with a lack of the 'AChR-like' antigen in the thymus.

The results reported here suggest that the component in thymocytes which cross-reacts with anti-AChR antibodies is a surface antigen. The fluoresence studies also demonstrate that the 'AChR-like' antigen on thymic lymphocytes is homogeneously distributed on the cell surface and that a similar number of antibody molecules are bound per cell under a given antibody concentration. It seems that the amount of antibodies reacting with thymocytes in anti-AChR sera is probably rather low or, alternatively, of very low affinity because the cross-reactivity could be observed only by using relatively high amounts of anti-AChR specific sera. We are attempting now to isolate by specific immunoadsorption and to identify the AChR cross-reacting material from the thymus.

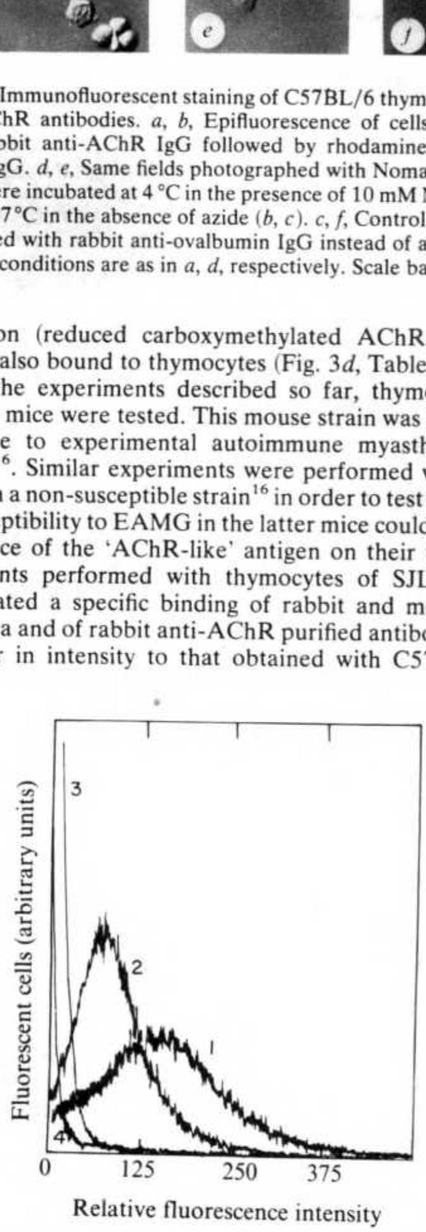

Fig. 2 Immunofluorescence profile of C57BL/6 thymocytes labelled with rabbit anti-AChR immunoglobulins (1, 2, 600 and 200 μg, respectively) and with rabbit anti-ovalbumin (3, 4, 600 and 200 μg, respectively). Fluorescein-conjugated goat anti-IgG was used for staining.

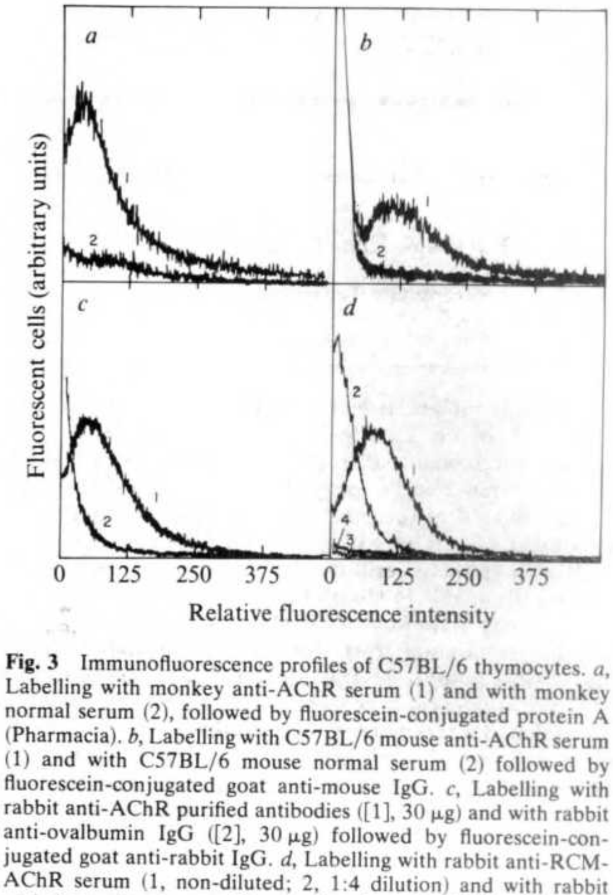

Fig. 3 Immunofluorescence profiles of C57BL/6 thymocytes. *a*, Labelling with monkey anti-AChR serum (1) and with monkey normal serum (2), followed by fluorescein-conjugated protein A (Pharmacia). *b*, Labelling with C57BL/6 mouse anti-AChR serum (1) and with C57BL/6 mouse normal serum (2) followed by fluorescein-conjugated goat anti-mouse IgG. *c*, Labelling with rabbit anti-AChR purified antibodies ([1], 30 μg) and with rabbit anti-ovalbumin IgG ([2], 30 μg) followed by fluorescein-conjugated goat anti-rabbit IgG. *d*, Labelling with rabbit anti-RCM-AChR serum (1, non-diluted; 2, 1:4 dilution) and with rabbit anti-ribonuclease serum (3, non-diluted, 4, 1:4 dilution) followed by fluorescein-conjugated goat anti-rabbit IgG.

It should be pointed out that we did not succeed in demonstrating any significant toxin-binding activity in thymocytes or thymic extracts. This is also in agreement with the finding that antibodies against a pharmacologically inactive RCM-AChR cross-react with thymus (Fig. 3*d*). These results suggest that the immunologically cross-reacting material on thymocytes is probably not an active nicotinic receptor. Nevertheless, an immunological cross-reactivity by itself could explain the association between the thymus and the neuromuscular junction in myasthenia, where the thymic antigen or a modified form of it could be the primary antigen in the spontaneous disease, or alternatively could be damaged by a cross-reactive autoimmune attack by anti-AChR antibodies. Previous reports have suggested that the immunological cross-reactivity between AChR and thymus could stem from myoid cells which were shown to develop to striated muscle fibres in cultures of thymus reticulum under selective medium conditions[17,18], or from some thymic epithelial cells which were shown to contain acetylcholine receptor[19].

The presence of anti-thymus antibodies has been demonstrated in a high percentage of myasthenic patients[7] and we could also detect binding of sera from myasthenics to mouse thymocytes. However, in the spontaneous disease, there is no direct evidence whether the immune response to thymus is a separate independent reaction or whether autoantibodies to AChR cross-react with the thymus. The present study provides direct evidence that anti-AChR antibodies can cross-react with the thymus.

We thank Mr Avigdor Petrank for his assistance in the FACS studies, and Dr Benjamin Geiger and Mr Daniel Bartfield for their help and discussions. G. T. was a visiting scientist from the University of Padova, Italy. This research was supported by grants from the Muscular Dystrophy Association of America, The United States–Israel Binational Science Foundation and the Los Angeles Chapter of the Myasthenia Gravis Foundation.

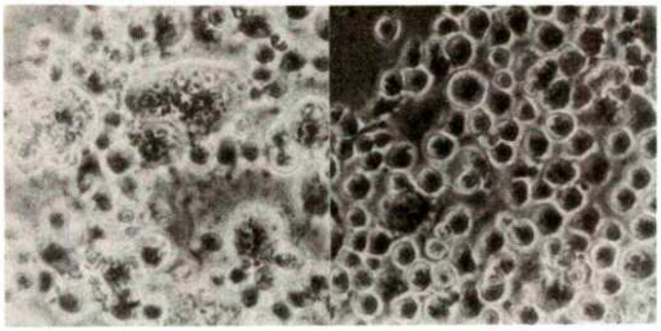
Epstein–Barr virus-induced cell fusion

Gary James Bayliss & Hans Wolf

Max von Pettenkofer Institute, Pettenkoferstr. 9a,
8000 München 2, FRG

Serological and molecular biological studies[1–3] have shown an association between Epstein–Barr virus (EBV) and nasopharyngeal carcinoma. Although it has been shown that the epithelioid tumour cells carry EBV genomes[4], they are apparently devoid of receptors for EBV (H.W., unpublished observations). Others have suggested that fusion of EBV carrying cells with epithelial cells may be the mode of entry of the virus into cells unable to absorb the virus and that this may be mediated by one of the known syncytium-forming viruses which inhabit the respiratory tract (for example, members of the paramyxovirus group). de Thé and colleagues suggested that intercellular bridges could be seen in NPC tumour material[5]. We have developed a technique which permits the preparation of stable monolayers of viable human lymphoblastoid cell lines[6]. Using this technique we have now demonstrated that EBV can induce fusion between EBV-superinfected lymphoblastoid cells and cells devoid of EBV receptors.



a *b*

Fig. 1 The formation of polykaryocytes in cultures of immobilized superinfected Raji cells. A stock of EBV prepared from P3HR1 cells was used to superinfect Raji cells as previously described[8]. After shaking at room temperature for 1 h, the cells were applied to plastic Petri plates coated with ALG. The infected, immobilized cultures were incubated at 37 °C. *a*, Raji cells superinfected with concentrated virus, 4 h post-infection. *b*, As *a*, but virus diluted 1 : 100. ×650.

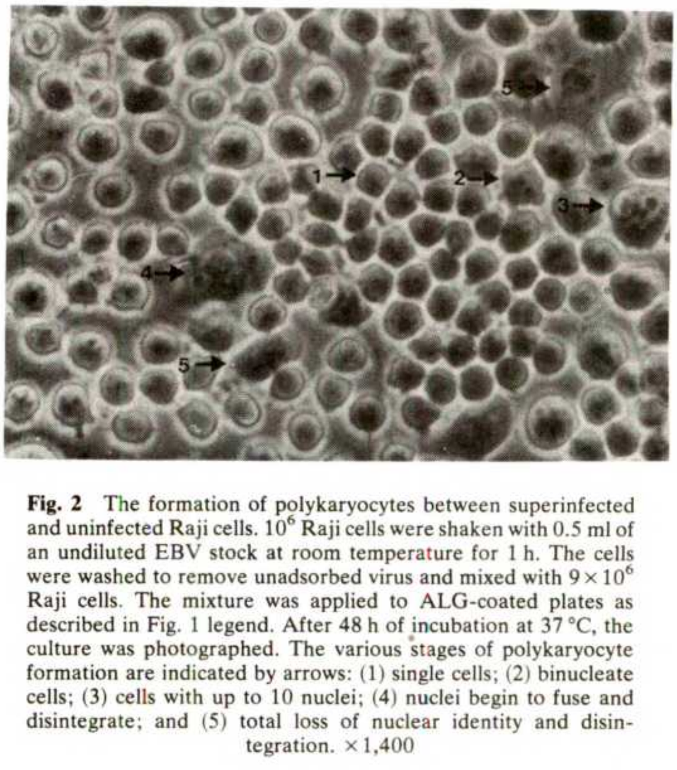


Fig. 2 The formation of polykaryocytes between superinfected and uninfected Raji cells. 10^6 Raji cells were shaken with 0.5 ml of an undiluted EBV stock at room temperature for 1 h. The cells were washed to remove unadsorbed virus and mixed with 9×10^6 Raji cells. The mixture was applied to ALG-coated plates as described in Fig. 1 legend. After 48 h of incubation at 37 °C, the culture was photographed. The various stages of polykaryocyte formation are indicated by arrows: (1) single cells; (2) binucleate cells; (3) cells with up to 10 nuclei; (4) nuclei begin to fuse and disintegrate; and (5) total loss of nuclear identity and disintegration. × 1,400

Raji cells, which carry the EBV genome but do not express early or late viral antigens, are susceptible to superinfection with EBV derived from the EBV-producing cell line P3HR1. Superinfected cells enter an abortive or productive cycle of virus replication depending on the multiplicity of infection. Productively infected cells synthesize viral DNA[7] and several virus-specified polypeptides[8] including early antigen (EA)[9] and viral capsid antigen (VCA)[10]. This superinfection system was used as a model to study the interaction of EBV-infected B-lymphoblastoid cells with one another and with unrelated cells. The response of uninfected Raji cells to immobilization on plastic surfaces coated with antilymphocyte globulin (ALG) has been described elsewhere[6]. When superinfected Raji cells were applied to ALG-coated plates in sufficient numbers to yield a confluent monolayer, polykaryocytes were observed within 2 h of immobilization (4 h after addition of the virus to the cells). Figure 1*a* shows a phase contrast photomicrograph of such a culture. Dilution of the virus stock used to superinfect the Raji cells leads to a diminution of the number of polykaryocytes

0028–0836/80/370164—02$01.00

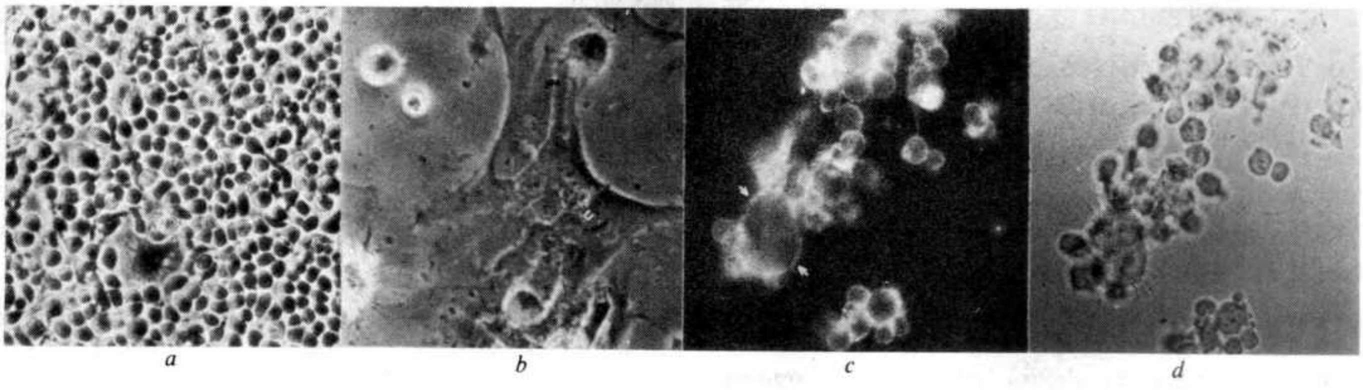

Fig. 3 The formation of polykaryocytes between infected Raji cells and cells devoid of EBV receptors. Raji cells were applied to ALG-coated plates to yield very sparse monolayers (approximately 10% confluent). After the cells had attached, virus was added and 1 h later either Jurkat (T-lymphoblastoid cells; *a*, *c*, *d*) or human embryo fibroblasts (*b*) were added to give a subconfluent monolayer. The cultures were incubated at 37 °C and photomicrographs prepared 20 h after infection. The cultures in *c* and *d* were stained with anti-T-cell serum. *c* Shows a polykaryocyte with T-cell membrane fluorescence. The arrows indicate areas where the polykaryocyte is free of adherent cells (see *d*) and shows clear membrane fluorescence. *d* Is a photograph of the same group of cells taken under normal light. At least three nuclei can be identified within the polykaryocyte. *a*, *b*, ×650; *c*, *d*, ×1,000.

observed (Fig. 1*b*; virus diluted 1:100). Immobilization of Raji cells without addition of exogenous EBV does not induce polykaryocyte formation. With minor modifications this technique can be used to titrate stocks of EBV. A similar series of experiments, in which infected cells were treated with sodium azide or cycloheximide, or in which cells were infected with UV-ray inactivated virus or virus treated with neutralizing antiserum, indicated that at least partial expression of EBV is required to induce cell fusion.

The high multiplicities of infection necessary to induce a full or partial virus reproductive cycle prevents observation of the interaction between infected and uninfected cells. To obviate this problem, superinfected Raji cells were washed to remove unadsorbed virus and mixed with uninfected Raji cells in a ratio of 1:10. The mixture of cells was applied to ALG-coated plates and the cells were allowed to attach as described above. After 48 h, numerous multinucleate cells could be observed and in some of the syncytia the nuclei had begun to disintegrate or coalesce. Figure 2 illustrates the various stages of syncytium formation.

These experiments show that EBV can induce fusion between cells having receptors for EBV, but not whether EBV can induce fusion between receptor-positive and -negative cells. We studied the interaction of superinfected Raji cells with human T-lymphoblastoid cells (Jurkat) or human embryo fibroblasts (HEF). Raji cells were applied to ALG-coated plates to give very sparse monolayers with a cell density of less than 10% of confluency. These cells were infected *in situ* by adding a stock of EBV; after the virus had been adsorbed by the Raji cells, Jurkat or HEF cells were added. After incubation at 37 °C for 20 h, the cultures were photographed (Fig. 3*a*, *b*). From these photographs it is apparent that the cells had fused giving rise to polykaryocytes. Fluorescent antibody staining of the cultures showed that the polykaryocytes contained EBV antigens (EA and VCA) and that the polykaryocytes formed between superinfected Raji cells and Jurkat cells had T-cell membrane determinants on their surface (Fig. 3*c*, *d*).

Our observations suggest that close cell-to-cell contact, as it occurs in closely packed monolayers, is necessary for the development of multinucleate cells. A close contact between epithelial cells and lymphocytes (which may carry EBV genomes) has been observed in the lymphoepithelium of Waldeyer's ring of the throat[11]. The exceptionally close contact between the lymphocytes and epithelial cells in this unique tissue may provide the necessary conditions for EBV-induced fusion between the two cell types. For further considerations of this aspect, and the relationship of EBV to other lymphoepithelial and undifferentiated carcinomas of the Waldeyer's ring see ref. 12.

In situ hybridization studies[13] with NPC tumour material indicate that the cancerous cells carry a heavy load of viral genomes. This could be achieved in one of two ways: either the virus is activated, enters into a lytic cycle and replicates independently of the host cell using virus-specified DNA polymerase[14] or, as in cell lines which carry the genome but cannot enter a lytic cycle, the viral DNA can be replicated using host replicative machinery (for example, see ref. 15). Lymphoblastoid cells in a lytic cycle which contain several thousand copies of the viral genome[16] could fuse with epithelial cells transferring its entire viral load. Tumour cells contain large quantities of viral DNA, the near diploid or near triploid karyotype and chromosomal abnormalities[17] fusion of EBV-carrying lymphocytes with epithelial cells could generate such abnormal cells. In addition the hybrid cell could then eliminate most of the genetic material originating from the lymphoblastoid cell and regain a near normal chromosome number. The efficiency with which EBV can induce cell fusion in tissue culture supports the hypothesis that EBV-induced cell fusion may be important in the infection of epithelial cells, which are normally refractory to infection by this virus, provided that certain conditions of virus activation and close cell contact are met.

We thank Mrs G. Deby for technical assistance and Dr Rodt for supplying the sera. The work was supported by a grant from the Deutsche Forschungsgemeinschaft (DFG Wo 227/2) and from the Sonderforschungsbereich 51.

Do 'lipidic particles' represent intermembrane attachment sites?

Rodman G. Miller

Institute of Histology and Embryology, University of Geneva Medical School, 1211 Geneva 4, Switzerland

Although freeze-fracture electron microscopy is normally analysed with the presumption that particles represent proteins embedded within the membrane, particles which appeared to represent inverted lipid micelles within membranes have been reported[1-4]. I have now confirmed the occurrence of particles in protein-free liposomes, but have found that they behave like intermembrane attachment sites rather than structures within a membrane.

Pits and particles have recently been described on freeze-fracture replicas of liposomes containing an equimolar ratio of cardiolipin and phosphatidylcholine[1]. Furthermore, several lipids which are capable of forming a hexagonal II phase will also form pits and particles on freeze-fractured membranes[2,3]. The interpretation of these results has been that these lipids are able to form inverted micelles, which have a similar organization to the hexagonal II phase, sandwiched between the leaflets of the membrane[1,2,4]. It has also been suggested that some of the particles seen in freeze-fractured biological membranes may also represent inverted lipid micelles in the centre of the membrane[1,2,4]. This is a serious suggestion since, thus far, freeze-fracture replicas have been analysed with the consideration that particles represent proteins (with or without a layer of adsorbed lipids and/or condensate) intercalated in the plane of the membrane. I have now studied a cardiolipin–phosphatidylcholine liposome system to define better the nature of the particles and pits in these membranes.

Multilamellar liposomes were prepared as follows: an ethanol solution of cardiolipin (Sigma) and phosphatidylcholine (egg yolk, Sigma) was dried under a stream of dry nitrogen and hydrated with buffer (100 mM NaCl, 10 mM Tris (*p*H 7.5) with 10% glycerol). The resulting suspension was vigorously shaken for 10 min and sonicated in a bath type sonicator for 10 min. Similar results to those presented have been obtained without glycerol in the buffer and by using the injection method of liposome preparation (see ref. 1 for example). Addition of calcium was performed by addition of an appropriate aliquot of the same buffer containing 10 mM $CaCl_2$ and mixing. Liposomes were quenched in partially solidified freon and freeze-fractured in a Balzers freeze-fracture device.

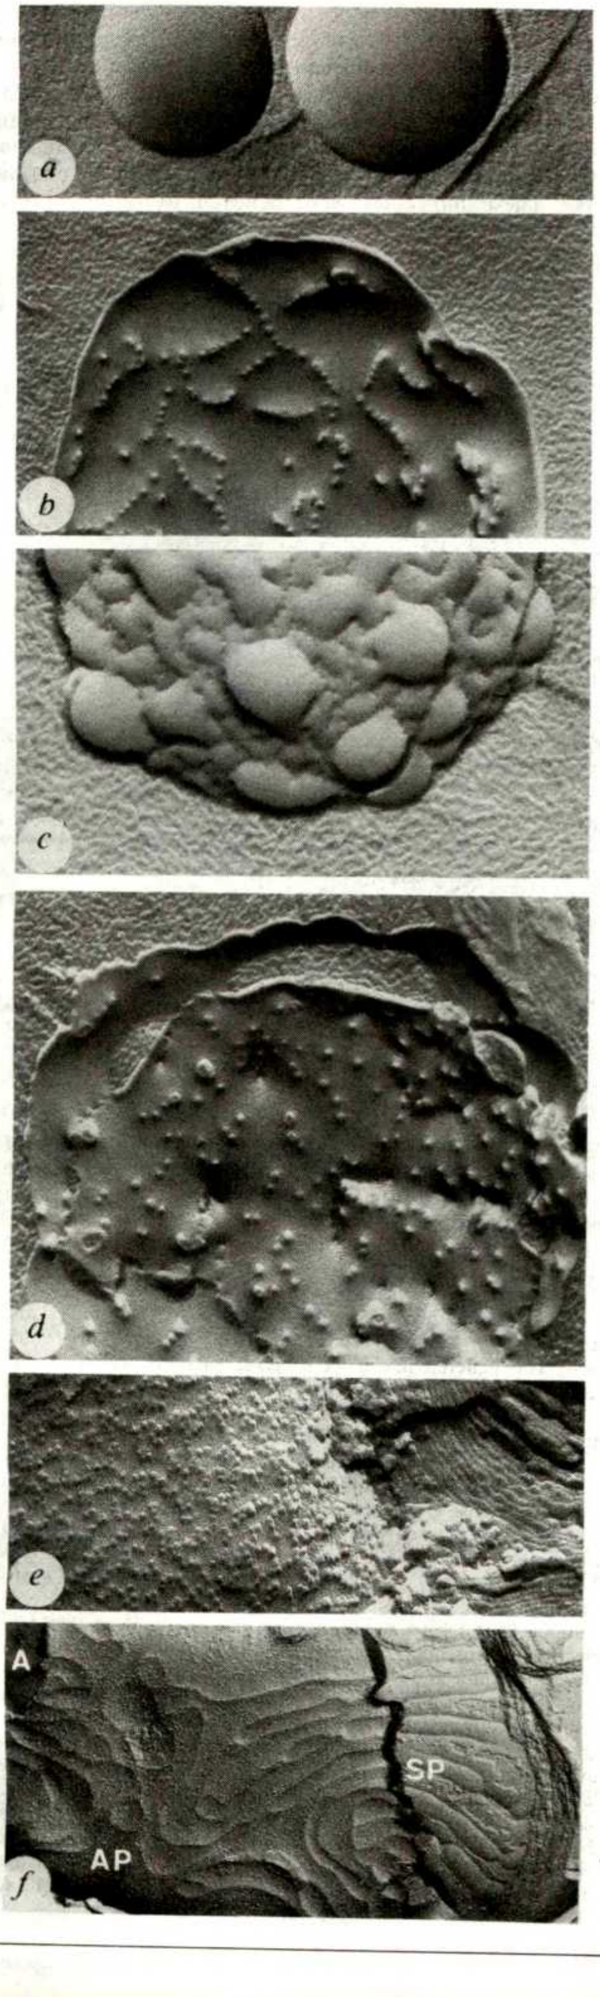
Multilamellar liposomes formed with an equimolar ratio of cardiolipin and phosphatidylcholine are spherical, smooth and do not contain particles or pits (Fig. 1*a*). The addition of calcium (2 mM final concentration) induces the appearance of particles and pits on some of the liposomes. In most of the liposomes which showed particles or pits, the fracture face exposed was that of the external membrane of the liposome, and contained either particles (Fig. 1*b*) or pits (Fig. 1*c*) but not a mixture of the two. In each case, the leaflet which contained the particles was the external leaflet (E-face) and the leaflet which contained the pits was the internal leaflet (P-face). No fractures which apparently represented the external membrane of a liposome contained pits on the E-face or particles on the P-face. Less than 5% of the liposomes were fractured such that internal membranes of the liposome were revealed. On those that were, I found fracture faces with either particles or pits, and on some occasions a mixture of both (Fig. 1*d*). Consistent with the report that calcium induces fusion in cardiolipin-containing liposomes[3], many liposomes were found that appeared to be partially fused. These will be the subject of a subsequent report from this laboratory (work in progress).

The location of the pits and particles on these membranes was not random: typically they appeared in linear arrays, the individual particles or pits being separated from each other by 12–40 nm. This indicates that long-range interactions are responsible for the location of the pits and particles. Linear arrays of particles occurred along the top of slight ridges on the fracture face, while linear arrays of pits occurred at the bottom of complementary valleys. This effect creates the quilt-like pattern seen in Fig. 1*b–d*. In preparations where the calcium concentration was increased to 6–10 mM, few liposomes remained intact and under the dissecting microscope, massive precipitation of the liposomes was observed. In replicas, the central region of the precipitate no longer appeared as individual bilayer membranes. However, at the edges of the precipitate, regions could be found which appeared to retain the bilayer configuration and which were characterized by high densities of either particles or pits (Fig. 1*e*).

Several observations must be reconciled in a hypothesis which attempts to explain the data: (1) the highly asymmetrical distribution of the particles and pits. In all cases, the outer membrane E-face contained particles while the P-face had pits; (2) the arrangement of the pits and particles into linear arrays; (3) the occurrence of the pits in valleys and particles on ridges of membrane contour; and (4) the absence of particles or pits on many membranes in the preparations. In Fig. 1*g–j*, I present several hypotheses which have been considered: in *g* the model of an inverted micelle in the centre of the membrane is symmetrical with respect to the membrane and cannot be expected to have long-range interactions to alter the contour of the membrane. In *h*, the membrane is distorted to produce a particle–pit pair which is asymmetric but does not have the potential for long-range interactions any further than the diameter of the pit and would not be expected to occur in valleys or ridges of membrane contour. In *i*, a variant of *h*, the production of a pit–particle pair is accompanied by a larger deformation of the membrane contour of a diameter, *x*. This model is asymmetrical, it could provide long-range interactions between the pits or particles up to a distance *x* (minimization of surface energy is expected to aggregate such particles), and the distribution of particles and pits on ridges and valleys, respectively, could be accounted for. That the particles do not appear on all regions of the membrane is not, however, accounted for. Finally, in *j*, the particles and pits are proposed to be attachment sites between two membranes. This model reconciles all the observed data: (1) Such attachments between two membranes necessitate the proximity of another membrane. An observed leaflet would demonstrate pits if the membrane to which it is attached is beneath the fracture plane, and particles if it is above the fracture plane. Both pits and particles would be seen only if the observed membrane is attached to membranes both above and below it. (2) If the attached points are mobile within the plane of the membranes, distension of the spaces between two such membranes can be expected to aggregate the points into a line or, in the extreme case, a cluster. (3) A row of points would be expected to alter the local contours of the membranes such that particles would appear at the tops of ridges and pits at the bottoms of valleys. This would produce the quilt-like pattern which is typical of these preparations; and (4) Although specific lipids (for example, cardiolipin in the presence of calcium) may be a necessary condition for the formation of these pits and particles, the ability to make contact (or maintain contact) with another membrane may be the limiting factor in the production of pits and particles.

Among morphologists, concern has arisen that many of the particles which have been presumed to be indicative of proteins may be purely lipidic. However, the present analysis suggests that lipidic particles may represent sites of membrane contact; this should greatly decrease occasions for concern in biological systems.

A more crucial question arising from the present analysis is



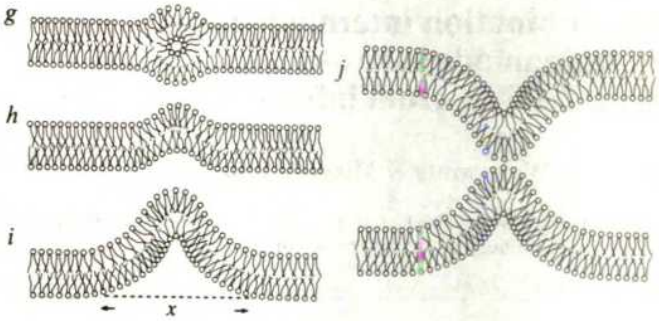


Fig. 1 *a*, Liposomes of 1:1 molar mixtures of cardiolipin:phosphatidylcholine before addition of calcium have membranes which are smooth and uninterrupted by pits or particles: ×80,000. *b*, Addition of calcium to a final concentration of 2 mM induces the appearance of particles on the outer leaflet of the liposome: ×60,000. From the same preparation as *b*: *c*, the inner membrane leaflet of the outer membranes of these liposomes show pits: ×80,000. And *d*, occasionally fractures expose membranes which are not the outer leaflet of the liposome. In these cases, pits, particles or mixtures of the two (as shown here) are present: ×65,000. *e*, When the concentration of calcium is increased to between 6 and 10 mM, precipitation of the liposomes is apparent. At least two phases are present, one with bilayer conformation and many pits or particles, and the other lamellae with no visible aqueous layer between the lamellae: ×80,000. *f*, Freeze fracture of a rat sciatic nerve frozen immediately after removal from the animal. A, axoplasm; AP, axolemmal P-face; SP, Schwann cell P-face: ×25,000. *g–j*, Several hypothetical models which may be considered to explain 'lipidic particles'. *g* and *h* are redrawn after ref. 2. See text for further details.

whether structures (of any material) which attach two membranes together are susceptible to relocation within the plane of the membranes when the membranes in which they are embedded are mechanically pulled apart (for example, by osmotic or freezing effects). In my work, I have found instances where such effects appear to be operating. Figure 1*f* is a particularly striking example of unfixed and non-cryoprotected myelinated nerve where it is believed that growth of ice has created quilt-like arrays of particles on the axolemmal P-face. These arrays are not seen in material which has been fixed. Arrays of this sort are believed to be indicative of structures which are visible in the plane of fracture and which link two membranes together. The location of tight junctions, gap junctions and other structures which link two membranes together may also be susceptible to relocation into clusters and quilt-like patterns as proposed.

I thank the members of this Institute for their help, and, in particular, D. Brown, E. Hooghe-Peters and P. Meda for help with the manuscript, and L. Orci for continuing encouragement. This work was supported by a grant from the Swiss NSF (3.120.77).

Visualization of genetic recombination intermediates of human adenovirus type 2 DNA from infected HeLa cells

Debra J. Wolgemuth & Ming-Ta Hsu

Department of Molecular Cell Biology, The Rockefeller University,
1230 York Avenue, New York, New York 10021

The study of recombination in prokaryotes has been facilitated by the availability of recombinational mutants and simple genetic elements such as phages and plasmids. These small but defined molecules of DNA have been especially useful for electron microscopic analysis of structural detail of molecules undergoing recombination both *in vivo* and *in vitro*[1–3]. A limitation in the structural analysis of plasmid recombination is the absolute number of recombining molecules which can be identified and analysed amidst a background of nonrecombining molecules[3]. This limitation would be of even greater consequence in studies of genetic recombination in animal cells. We therefore chose virus-infected animal cells as a model system for the study of the molecular mechanism of genetic recombination in higher organisms. HeLa cells infected with adenovirus serotype 2 (Ad-2) offer several advantages for studying recombination: (1) the virus contains a small and well characterized genome of about 35 kilobases; (2) a large amount of Ad-2 DNA is accumulated during lytic infection and host DNA synthesis is suppressed[4]; (3) Ad-2 recombines at a very high frequency[5,6]; and (4) similar to phages, animal viruses and Ad-2 in particular are believed to use many of the host cell's enzymes in necessary metabolic processes, presumably including recombination. In this study we used electron microscopic techniques to visualize the structures of *in vivo* Ad-2 DNA recombination intermediates. Molecules were observed with structures at putative cross-over points which were consistent with the molecular mechanism of recombination proposed by Holliday[7]. In addition, we observed Ad-2 DNA molecules engaged in recombination which were simultaneously serving as templates for replication and/or transcription. To the best of our knowledge, this is the first visualization of *in vivo* recombination intermediates of discrete DNA molecules isolated from eukaryotic cells.

Nucleoprotein complexes were isolated from Ad-2 infected HeLa cells late in infection (20–25 h), a time when viral DNA synthesis and unpackaged viral DNA are maximal[4]. To minimize the cellular DNA background, Ad-2 nucleoprotein complexes were selectively extracted from purified nuclei by the procedures of Wilhelm *et al.*[8] as described in the legend to Fig. 1 and in ref. 9. Aliquots from the sucrose density gradient-fractionated Ad-2 nucleoprotein complexes were prepared for electron microscopy as described by Davis *et al.*[10]. At 20 h post-infection the majority (~70%) of the molecules observed were found to be duplex unit-length Ad-2 DNA. Molecules engaged in viral DNA replication, transcription, and simultaneous replication and transcription were observed and are discussed in detail elsewhere[9].

A small fraction (<1%) of molecules were observed which were characterized by the intimate association of what appeared to be two complete molecules of Ad-2 DNA. Such molecules were followed along their entire lengths under high magnification (~45,000×), photographs were made, and lengths measured to determine the nature of this association. Typical molecules are shown in Fig. 1. Two unit length molecules of Ad-2 DNA are joined at a region of sequence homology (as judged by position in the genome) wherein a cross-over structure can be seen (Fig. 1, inset). Such structures, clearly distinguishable in ~10% of the identified recombination intermediates, were most probably generated by a local denaturation in the region of cross-over[3] allowing visualization of the configuration of the participating strands. This configuration would be predicted from a Holliday-type model of recombination[7] and has been visualized previously with plasmid DNAs[3]. These molecules were believed to represent true

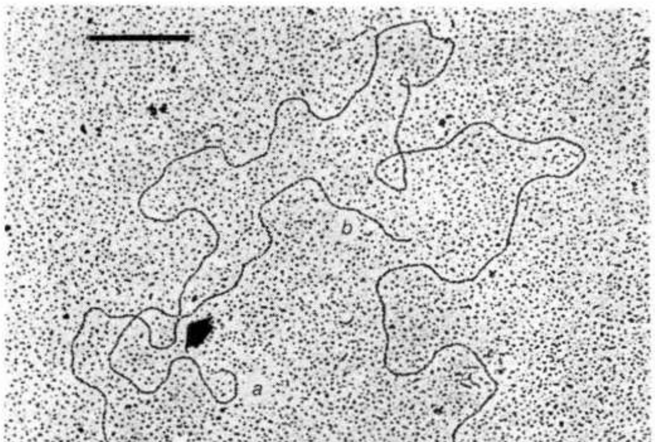

Fig. 1 Electron micrograph of a recombination intermediate of two molecules of Ad-2 DNA. Ad-2 nucleoprotein complexes were selectively extracted from Ad-2 infected HeLa cell nuclei by a modified procedure[9] of Wilhelm *et al.*[8]. Twenty to 24 h post-infection, the cells were pelleted and resuspended in TITE buffer (20 mM Tris, 100 mM NaCl, 0.02% Triton X-100, 2 mM EDTA *p*H 7.4) and homogenized in a tight fitting dounce at 0 °C. The homogenate was layered on 10% sucrose in TITE buffer and centrifuged for 5 min at 500 r.p.m. in a Damon IEC–6000 centrifuge. The pelleted nuclei were resuspended in TEAD buffer [20 mM Tris, 2 mM EDTA, 50 mM $(NH_4)_2SO_4$, 0.1 mM dithiothreitol, *p*H 7.9] and lysed by adding, drop by drop, 2 M $(NH_4)_2SO_4$ to a final concentration of 0.2 M. The lysate was allowed to stand for 10 min on ice and then was centrifuged for 10 min at 10,000*g*. The resulting supernatant or S200 was either layered directly onto 10–60% sucrose gradients in TEAD buffer[8] or was treated with 0.25% sarkosyl and resolved in a 15–30% sucrose gradient containing 10 mM potassium phosphate, *p*H 7.9, 2 mM EDTA, a 0.25 to 0% sarkosyl gradient and 0.25% glutaraldehyde[9]. Centrifugation was in an SW40 rotor at 4 °C for 17 h at 25,000 r.p.m. Various fractions from the sucrose gradient were analysed by electron microscopy. This particular preparation was spread in 50% formamide as described previously[10]. The cross-over point in the recombining molecules (large arrowhead) is enlarged in the inset on the lower right. The thin curved arrow in the inset indicates an overlap between strands which is clearly distinguishable from the Holliday-type structure indicated by the large arrowhead. The length of arm *a* (1.65 μm) is equal to arm *b* (1.64 μm), and *c* (10.68 μm) is equal to *d* (10.60 μm). The sum of *a*, *b*, *c* and *d* is 24.57 μm which is equal to two unit-length Ad-2 genomes (the average length of the intact Ad-2 DNA molecules illustrated in this study is 11.82 ± 0.41 μm). Scale bars, 0.5 μm large micrograph and 0.05 μm inset.

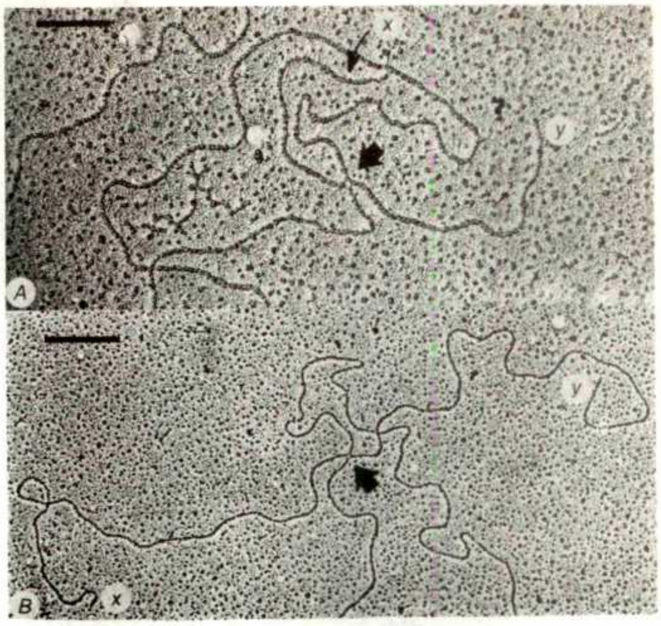
0028-0836/80/370168—04$01.00

Fig. 2 Electron micrographs of Ad-2 molecules with Holliday-type structures at various distances along the genomes. Each photograph shows a close-up of the Holliday structure (arrow) and one of the two pairs of equal length arms. In (*A*), arm *x* is equal to *y* and represents 8.5% of the genome length, a distance closer to the ends than in the molecules shown in Fig. 1 where the Holliday structure lies about at 13.5% of the genome length. In (*B*), *x* is equal to *y* and the Holliday structure is located at a point about 29.8% from an end of AD-2 genome. Preparations were made as described in Fig. 1 legend. Scale bars 0.2 μm (*A*) and 0.4 μm (*B*).



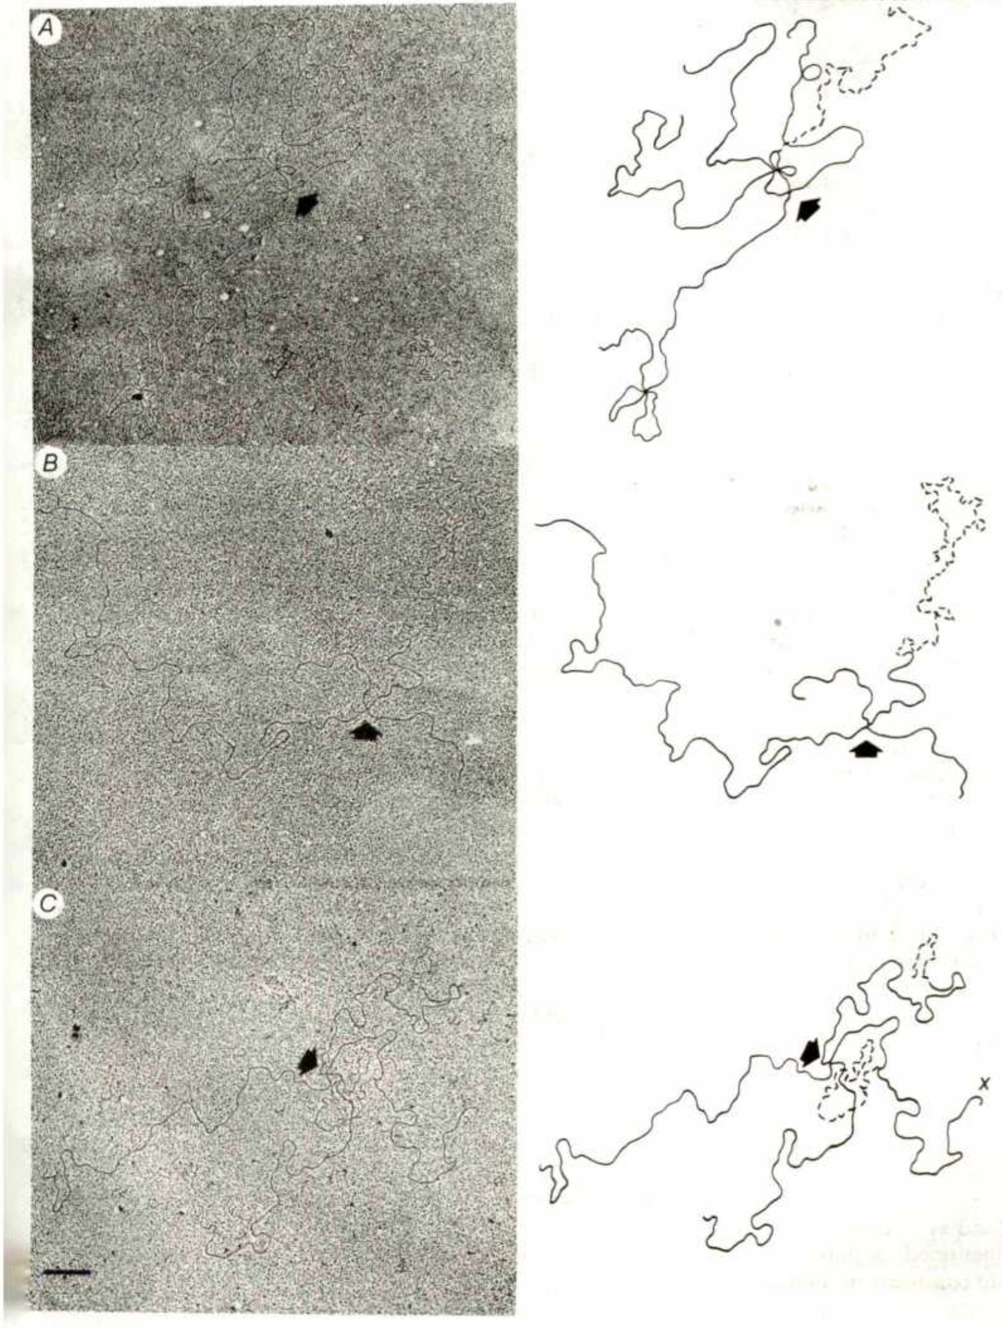


Fig. 3 Electron micrographs and interpretive tracings of Ad-2 recombination intermediates simultaneously engaged in DNA replication. The large arrowhead in each photograph and tracing indicates the point of putative cross-over. Double-stranded DNA is indicated by the solid black line; single-stranded DNA by the dashed line. *A*, Recombination involving an intact double-stranded unit length genome and a type I replication intermediate. The single-stranded displaced parental strand (dashed line) can be seen in the upper right. The sum of the four double-stranded arms is equal to two complete Ad-2 genomes. *B*, Recombination between an intact double-stranded Ad-2 molecule and a presumptive type II intermediate which is partially single-stranded and partially double-stranded. The cross-over point is between double-stranded regions of the two molecules. *C*, Recombination between two molecules containing both type I and type II replicative molecules. The sum of the three completely double-stranded arms and the one double-stranded and single-stranded arm is equal to two Ad-2 genome lengths. The single-stranded branch in the centre of the photograph represents the displaced parental strand complementary to one of the strands in the arm indicated as *X*. Cross-over junctions are located 41%, 16% and 46% along the genome lengths in *A*, *B* and *C*, respectively. The Holliday-type structure is visible in *A* but not in *B* or *C*. Scale bar, 0.5 μm.

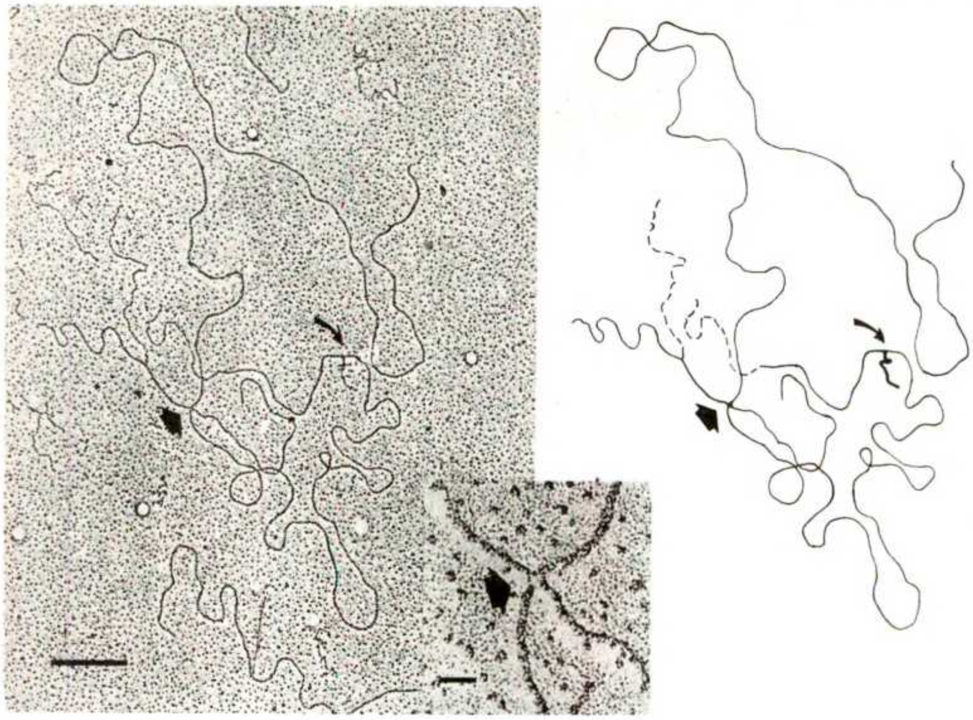

Fig. 4 Electron micrographs and interpretive tracing of recombination intermediate between replicative and transcriptionally active Ad-2 DNA molecules. The putative cross-over point shows a Holliday-type structure (indicated by the large arrowhead and enlarged in the inset). The curved arrow and heavy black line indicate a nascent RNA transcript (discussed in detail in ref. 9). Both type I and type II replication intermediates are seen. The single-stranded portions of these molecules are indicated by dashed lines; the double-stranded portions by the solid lines. Scale bars 0.5 μm large photomicrograph, and 0.05 μm inset.

recombination intermediates according to the following criteria: (1) the structure contained two sets of arms of equal length ($a = b$ and $c = d$ in Fig. 1) from the point of cross-over; (2) the sum of the lengths of the four arms was equal to two unit-length Ad-2 genomes; (3) the highly characteristic appearance of the strands of the molecules at the recombination juncture was observed and these structures were clearly distinguished from mere overlaps (curved arrow, inset to Fig. 1); and (4) such structures were never observed between molecules of purified SV40 DNA added to the preparation. As further illustrated in Fig. 2, these points of putative cross-over were found at various regions of the genome.

Recombination intermediates in which portions of the recombining Ad-2 genomes were apparently replicating were also observed (Fig. 3). The structure of replicating molecules of Ad-2 DNA has been described previously (reviewed in ref. 11). Briefly, Ad-2 DNA replication proceeds in a 5′ to 3′ direction from either end of the duplex molecule, displacing one of the parental strands. The resulting replicating intermediate (type I intermediate) contains two double-stranded branches and one or more single-stranded branches equal to the length of one of the double-stranded branches. For the replication of the displaced parental strand, the predominant mode of synthesis involves initiation at the 3′ end, generating an intermediate with single-stranded portions at one end of the molecule (type II intermediate). As can be seen in Fig. 3 (*A–C*), both types of replicative intermediates were found to be engaged in the recombination process. The recombination intermediate in Fig. 3*A* involves a unit-length double-stranded molecule and a type I replicating molecule with its characteristic fork and displaced parental strand. In Fig. 3*B*, a type II molecule and an intact unit length double-stranded molecule are involved in recombination. Both type I and type II replicating molecules are involved in the recombination event depicted in Fig. 3*C*. An additional category of recombining and replicating molecules was identified which was comprised of more complex structures consisting of recombination intermediates with single-stranded branches at the cross-over point. Analysis of these molecules, which may represent recombination events involving the displaced parental strand, analagous to the model for recombination proposed by Meselson and Radding[12], is under way. One further template activity was identified in molecules undergoing recombination: in addition to consisting of replicating molecules of both type I and type II, one of the recombining molecules shown in Fig. 4 also carries an RNA transcript. It is clear that the recombination event does not involve a sequestered group of molecules in these animal cells as they are simultaneously available to DNA and RNA polymerases.

These observations constitute direct structural evidence for the physical associations between recombining molecules predicted from the model of genetic recombination proposed by Holliday[7] and previously observed in prokaryotes[3]. A feature of this model is a reciprocal exchange between the two genomes with no requirement for DNA synthesis other than a repair-type. Our observation of recombination between non-replicating Ad-2 molecules (Figs 1 and 2) and between replicating molecules but not involving the displaced parental strand (Figs 3 and 4) lends further support to the Holliday-type model of recombination as one possible mechanism for accomplishing genetic recombination during Ad-2 lytic infection. We believe that this is the first time such *in vivo* recombination intermediate molecules have been visualized after isolation from animal cells. The formation of recombinant DNA intermediates between exogenous plasmid molecules in the presence of an extract from unfertilized *Xenopus laevis* eggs reported by Benbow and Krauss[13] was generated totally *in vitro*. Since animal virus genomes are limited in the amount of genetic information they can carry, they are believed to utilize a variety of cellular products to accomplish metabolic events. Elucidation of the molecular mechanisms of recombination in animal viruses in somatic cells should yield information on the genetic recombination process that occurs during meiosis in germ cells.

We thank Dr James E. Darnell Jr for continued support, Dr Selina Chen-Kiang for helpful discussion, Ho-Yun Yu for technical assistance and Lois Cousseau for help in preparing the manuscript. Indomethacin and inhibition of protein kinase reactions

Said A. Goueli & Khalil Ahmed

Toxicology Research Laboratory, Department of Laboratory Medicine and Pathology, University of Minnesota, VA Medical Center, Minneapolis, Minnesota 55417

Indomethacin, an inhibitor of prostaglandin biosynthesis, is useful in studies aimed at understanding the metabolism and physiological function of prostaglandins[1]. A recent report[2] showing that indomethacin at 10^{-7} M potently inhibits the cyclic AMP-dependent protein kinases (cAMP-PrK) from ileal mucosa in the presence or absence of cyclic AMP, suggests how indomethacin may antagonize prostaglandin action on ileal mucosa. It also suggests that indomethacin might be useful in studying the properties and functions of protein kinase reactions. Inhibitors of prostaglandin biosynthesis, such as sodium salicylate and acetylsalicylate, at concentrations near 10^{-2} M, have been shown to inhibit bovine diaphragm protein kinase only in the presence of cAMP, while stimulating it in the absence of cAMP[3]. We report here that complete inhibition of cAMP-PrKs by indomethacin requires a concentration of 10^{-3} M and is not tissue-specific, and that the effect of indomethacin is concentration dependent above 2×10^{-4} M for the cAMP-dependent, and above 10^{-3} M for cAMP-independent PrKs. These results contrast previous ones[2].

Cyclic AMP-dependent protein kinase was purified from rabbit ileal mucosa and rat liver cytosol by a modification of methods described earlier[4,5]. Rabbits (~4 kg) were used as the source of ileal tissue. Ilea were rinsed with cold distilled water, and the mucosa was isolated by stripping it off the muscle tissue. Sprague–Dawley rats (weighing 250–300 g, from ARS/Sprague Dawley) were used as the source of liver tissue. Protein kinases I and II, and their catalytic subunit, were purified through DEAE-cellulose and hydroxyapatite steps. Peak I was eluted from DEAE-cellulose at less than 0.1 M NaCl, and peak II at 0.15–0.2 M NaCl. The activity ratios (minus cAMP/plus cAMP) of peaks I, II and the catalytic subunit in the presence of 2 μM cAMP were 0.4, 0.5 and >0.9, respectively, for the rabbit ileum preparation, and 0.17, 0.33 and >0.95, respectively, for rat liver preparations. The ratio of peak I to peak II was 15:85 and 45:55 for rabbit ileum and rat liver, respectively. Each of the three activities was inhibited by the classical cytosol cAMP-PrK inhibitor[6]. A cAMP-independent liver nuclear protein kinase was purified using DEAE-Sephadex and partially (30%) dephosphorylated phosvitin (DPV) affinity chromatography (unpublished work). The enzyme had insignificant activity toward lysine-rich histones, but was very active towards DPV, casein and liver nuclear endogenous non-histone proteins (NHP) as substrates. It was neither stimulated by cAMP nor inhibited by the cAMP-PrK inhibitor. Indomethacin solution was prepared by titration with 0.1 M NaOH of an aqueous suspension of indomethacin until the solution was clear (final *p*H 9.0). The extinction coefficient of this solution was 16,200 and 6,300 at 260 and 319 nm, respectively. This suggests that indomethacin was stable in these experimental conditions. Experiments were also carried out with indomethacin dissolved in ethanol; in this case an appropriate amount of ethanol was added in control reactions. The results obtained were not dependent on the method of preparing the indomethacin solution.

As shown in Fig. 1, indomethacin at 10^{-4} M had no significant effect on any of the rabbit ileum mucosa cAMP-PrKs in the presence or absence of cAMP. Concentrations below 10^{-4} M were equally ineffective (data not given). The same result was

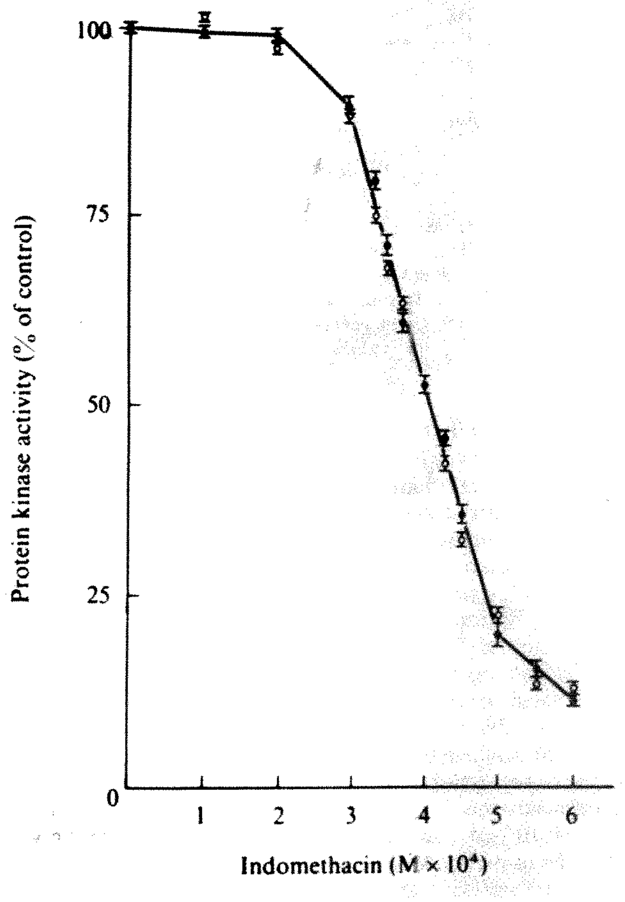

Fig. 1 Effect of varying concentrations of indomethacin on cAMP-PrKs from rabbit ileum mucosa, in the presence or absence of cAMP. The standard reaction medium for assaying cAMP-PrK was Tris-HCl, *p*H 7.45 (30 mM, 37 °C); LRH or protamine sulphate (1–5 mg ml^{-1}); $MgCl_2$ (10.0 mM); [γ-^{32}P]ATP, (0.2 mM, 30–50 μCi μmol^{-1}); with or without cAMP (2 μM); and, enzyme protein (0.04–0.2 mg ml^{-1}) in a final volume of 0.25 ml. The enzyme was allowed 20–45 min prior contact at 37 °C with all the reactants except $MgCl_2$ and [γ-^{32}P]ATP which were added together to initiate the protein kinase reaction, following which aliquots (40 μl) were removed at 0, 4, 8 and 12 min. This material was rapidly spotted on P-81 paper, and the radioactivity incorporated in protein substrates was determined as described by Corbin and Reimann[12]. The assay medium for cAMP-independent nuclear protein kinase consisted of Tris-HCl, *p*H 7.45 (30 mM, 37 °C); DPV (2 mg ml^{-1}); $MgCl_2$ (4 mM): [γ-^{32}P]ATP (3 mM, 2–5 μCi μmol^{-1}), in a final reaction volume of 0.25 ml. The details of incubation were the same as described above. The amount of radioactivity incorporated in DPV was determined as described by Goueli *et al.*[13]. Each data point represents a mean of 10 experimental values ± s.e.m. for each tested enzyme; ●, plus cAMP; ○, minus cAMP. Statistical analysis using Student's *t*-test between activity values in the presence of 0, 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5} and 10^{-4} M indomethacin showed no significant differences at 1% level. All protein determinations were according to Bensadoun and Weinstein[14] using BSA, DPV and lysine-rich histones as standards. In some experiments α-glycerophosphate (*p*H 7.4, 37 °C) was used in place of Tris-HCl (*p*H 7.45, 37 °C) as buffer in protein kinase assays in the presence or absence of indomethacin. Change of buffer did not alter the results described above.

0028–0836/80/370171—02$01.00

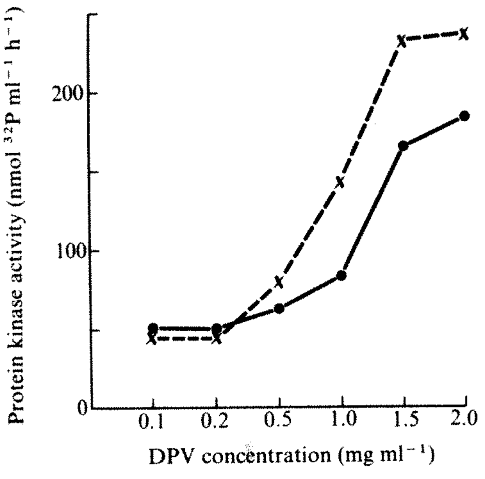

Fig. 2 Effect of varying concentrations of DPV on cAMP-independent nuclear protein kinase activity in the absence or presence of 10^{-3} M indomethacin. The details of assay were as described in Fig. 1 legend. ●, No indomethacin; x, 10^{-3} M indomethacin. Each point represents a mean of three different values ± s.e.m.

obtained with a number of different enzyme preparations, for example liver protein kinase peaks I, II and the catalytic subunit, bovine heart protein kinase peak II (data not shown). Also, the order of addition of various reactants, or the duration of prior contact of the enzyme with the drug, was without effect: the incubation of enzyme with the drug for up to 45 min at 30°C, or 20 min at 37°C, gave the same results as when no prior contact between drug and enzyme was allowed. Addition of 1 mM dithiothreitol had no effect on the protein kinase activity either in the presence or absence of indomethacin. When indomethacin concentration was increased to 10^{-3} M, all of the cAMP-dependent enzymes tested were inhibited, in the presence or absence of cAMP. These findings are in contrast to the previous report[2] which showed that inhibition by indomethacin was time dependent and maximal at a concentration of 10^{-7} M. Only at concentrations of indomethacin of 2×10^{-4} M or higher was there an inhibition of the ileal mucosa enzyme, as well as enzymes from other tissues. The concentration of the inhibitor required for 50% inhibition of the enzyme[7], ID_{50}, for the ileal mucosa enzyme was 6×10^{-4} M, and similar values of ID_{50} were obtained when enzymes from other tissues were tested. We also examined the endogenous incorporation of ^{32}P into cAMP-PrKs. Again, at concentrations of indomethacin above 10^{-4} M, the pattern of inhibition was similar to that noted when protamine or lysine-rich histones were used as substrates (data not given). Thus, our results suggest that indomethacin is not a potent inhibitor of cytosol protein kinase reaction and that the inhibitory effect is not specific for any of the kinases examined. This is similar to the observation that sodium salicylate at 10^{-2} M inhibited the kinase activity by 50% but was without effect at 10^{-3} or less[3].

The effect of indomethacin on a nuclear cAMP-independent protein kinase active toward DPV was also studied. We found that indomethacin did not inhibit this particular reaction, even at a concentration of 5×10^{-4} M; rather, a small stimulation (20–25%) of the kinase activity was observed in these conditions (data not shown). However, at higher concentrations (for example at 10^{-3} M), a small inhibition (25%) of the enzyme activity became apparent. Thus, it appears that this cAMP-independent kinase activity is even more insensitive to indomethacin than that dependent on cAMP. Furthermore, when liver chromosomal NHP was used as substrate for the cAMP-independent PrK reaction, the pattern of inhibition by indomethacin was similar to that observed with DPV as substrate (about 25% inhibition was noted at 10^{-3} M indomethacin).

To determine whether or not substrate concentration modified the indomethacin effect in this reaction, we tested the action of the drug on nuclear protein kinase activity at different concentrations of DPV in the reaction. Figure 2 shows that in the presence of 10^{-3} M indomethacin, this protein kinase reaction was only slightly inhibited in the presence of DPV at a concentration of about 0.2 mg ml^{-1}. However, at higher substrate concentrations (0.5–2.0 mg ml^{-1}) a stimulation of the kinase activity was noted. The above results suggest that indomethacin binds to DPV (a model acidic protein substrate) and lysine-rich histones or protamine (basic protein substrates) in a manner that influences their activity as substrates. It appears that the drug renders a more favourable conformation to DPV and a less favourable conformation to histone or protamine in the respective protein kinase reactions. This is somewhat analogous to the observed *in vitro* effects of polyamines on various protein kinase reactions in the presence of acidic or basic protein substrates[8]. However, note that binding of the drug to the enzyme itself (presumably with low affinity) to produce these changes cannot be excluded. The avid binding of indomethacin to plasma proteins has been reported; over 90% of indomethacin in the blood is bound to plasma proteins and only 10% is free for therapeutic effect[1]. To test whether or not indomethacin binding to proteins in the reaction was reversible, we added 2–10 mg ml^{-1} of bovine serum albumin (BSA) to the reaction in the presence and absence of indomethacin. BSA had no effect on the activity in the absence of indomethacin, but in its presence it completely reversed the inhibitory effect of 10^{-3} M indomethacin on cAMP-PrKs, suggesting that the indomethacin inhibition was reversible (data not shown). This is also in contrast with the previous conclusion[2] on the nature of indomethacin interaction with the enzyme.

The reason for marked differences between our results and those of Kantor and Hampton[2] is not clear. However, we have used a number of different sources of the kinases which have yielded similar results. The general properties of these enzymes are analogous to those reported in the literature. It is well known that cytosol protein kinases from a variety of cells behave similarly; the only variation is demonstrated in the ratio pf peaks I and II without any significant differences in enzymatic properties between peak I enzymes isolated from different tissues[9,10]. Thus, our results indicate that the indomethacin effect is not specific for any of the cAMP-PrKs, regardless of their source, and that complete inhibition of all of the enzymes requires 10^{-3} M concentration of the drug. Similarly, a variety of other enzymes is also known to be inhibited by indomethacin at concentrations in the range of 10^{-5}–10^{-4} M (ref. 11). Such effects of indomethacin, apparent only at higher concentrations, may contribute to the toxic manifestations of indomethacin, rather than reflecting a mechanism of therapeutic action *in vivo*[11].

This work was supported in part by funds from the Veterans Administration Medical Research Fund and from research grant CA-15062 from the D.H.E.W. We thank Mr Alan T. Davis and Miss C. Allison Hughes for their help. Bovine heart cAMP-PrK was from Sigma.

BOOK REVIEWS

Human behaviour: do the genes have it?

David P. Barash

Darwinism and Human Affairs. By Richard D. Alexander. Pp. 317. (University of Washington Press/Pitman: 1980.) $14.95, £9.50.

In his collected *Letters,* John Keats once wrote:

> I go amongst the fields and catch a glimpse of a stoat or a field mouse peeping out of the withered grass. The creature hath a purpose and its eyes are bright with it. I go amongst the buildings of a city and I see a man hurrying along — to what? The creature hath a purpose and its eyes are bright with it.

We may derive two inferences from Keats's poetic prose: (1) living things have a purpose, and (2) purpose is shared by human beings and animals. Unlike poets, who delight in it, scientists typically are trained to run the other way when 'purpose' rears its head. Nonetheless, this seemingly unscientific djinn keeps popping up in modern evolutionary biology. And, thanks to W.D. Hamilton's updating of Darwin, we are finally groping toward an understanding of that purpose: maximization of inclusive fitness. It is becoming increasingly clear that living things go about their business in a way that projects a maximum number of their genes into succeeding generations. Better yet, that *is* their business — and hence their purpose. (Alternatively, Richard Dawkins has emphasized that perhaps it is really the genes who are running the show.)

Like Wilson's *On Human Nature,* this book by Richard Alexander argues that inclusive fitness maximization is a philosopher's stone for understanding human behaviour. It fits well into the current sociology of sociobiology. For some reason, sociobiology has emerged primarily as a US–Britain concord, while continental Europe still contributes largely to ethology rather than its neo-Darwinian cousin. In addition, the British school has maintained a deafening silence on *Homo sapiens,* whereas the Americans are increasingly turning their attentions to the human species. Both groups, however, admire inclusive fitness. Indeed, sociobiology seems to have passed the stage of Thomas Kuhn's paradigmatic revolution and entered into the more extended phase of 'puzzle solving' or 'normal science'.

Alexander's book has its quirks: in 317 pages the word sociobiology is not once volunteered (signs of alpha male–male competition within the field). His prose is often turgid, and his presentation elaborate and convoluted. For example, we are served up Alexander's critique of anthropologist Marshall Sahlins's denial of Alexander's interpretation of Sahlins's work on reciprocity in primitive societies. Sometimes, however, he rises to near-poetry:

> Happiness . . . is eating and sex and parenthood and warmth and touching and ownership and giving and receiving and loving and being loved; it is the cessation of pain and the onset of pleasure; it is finding a way to win; it is having a magnificent idea or a grandchild.

But Alexander isn't Keats, and biology is never far away: "Happiness is a means to reproduction".

Human sociobiology is more than just inclusive fitness theory, but regrettably, we find no mention of male–female differences and parental investment theory, or of parent–offspring conflict. Even sexual selection, a current rage among most sociobiologists, receives short shrift. Although he is at pains to clarify that sociobiology does not imply genetic determinism, Alexander seems naively untouched by the vigorous and specific political objections that others have raised. In the conclusion of his *Origin of Species,* Darwin rather diffidently suggested that "light will be shed" on human beings as well. With light often comes heat. Some of the recent heat deserves considering, if only to refute it: for example, because of its emphasis on the biological unity of *Homo sapiens,* human sociobiology is a potentially potent antidote to racism.

Alexander has steeped himself in anthropology and the results are rewarding: both data and theory on cross-cousin marriage as an adjunct to incest avoidance, more original material on the mother's brother phenomenon, documentation on the overwhelming importance of kin and the curious phenomenon of self-deception, which the author suggests may help explain the reluctance of many to accept the findings of sociobiology applied to themselves. In many ways, this work is a *tour de force,* repeating and elaborating Alexander's many cogent arguments and original presentations of the past few years. He suggests a provocative view of justice, in which "laws function to place limits on reproductive striving", and an ingenious if somewhat disillusioning approach to right and wrong. His usually tight reasoning is less convincing, however, in a concluding treatment of the rise of nation-states, a subject to which evolutionary biology seems to offer little beyond debatable, *post hoc* interpretations.

Homo sapiens is undoubtedly the best-known and most widely studied species on our planet. And yet, ironically, the data base from which sociobiological propositions can be tested is extraordinarily unsatisfying. Alexander relies heavily on G.P. Murdoch's cross-cultural samples and upon the Human Relations Area File. As one who desires to paint in broad strokes on a world-wide canvas, he has no alternative, although anthropologists are (or should be) painfully aware that the HRAF especially is a nightmarish potpourri, ranging unpredictably from careful, quantitative documentation to mere anecdote. It is all we have, however, and therefore its use is justified. But nonetheless, numbers gleaned from such a source derive a reified exaltation that they only rarely merit. In human sociobiology, as in any other science, conclusions are only as robust as the data and, except in recent studies (often conducted specifically to test evolutionary hypotheses), these data tend to be woefully inadequate.

Nonetheless, human sociobiology comes to upgrade social science, not to replace it. Julian Huxley once warned biologists against "nothing butism", the notion that because we are animals we are necessarily nothing but animals. The warning is well taken, but can be turned around with equal force: just because human behaviour is largely the product of social learning and cultural tradition, we should not assume that our behaviour derives from "nothing but" these experiences. We are special, but we are also animals nonetheless, and as in most dichotomies the truth doubtless lies somewhere in between.

Critics are justified in rejecting "just so stories", and to his credit Alexander is especially adroit at establishing falsifiable hypotheses. Animal studies should not be uncritically extrapolated between species, and certainly this includes human beings. However, research on animals can provide propositions about the manner in which natural selection appears to act upon

New and recent Biology titles from Edward Arnold

Ancient Woodland its history, vegetation and uses in England
Oliver Rackham
'Oliver Rackam has produced a masterpiece.' *Arboricultural Journal*
Starting from a picture of the prehistoric wildwood, derived from many sources, he shows how the species composition of woodland has changed, often as a result of management, and how the variety of woodland types still relates to the original mosaic of the wildwood.
Boards £50 416 pages

Environmental Biology
E.J.W. Barrington, F.R.S.
Resource and Environmental Sciences Series
A remarkably unified text which shows how plants and animals have responded to the problems of life in diverse environments — both marine and terrestrial — in different manners. While using a wide variety of plant and animal species to illustrate particular biological principles, Professor Barrington also considers each topic in relation to the success of the organism in coping with its environment.
Paper £5.95 256 pages

Quaternary Palaeoecology
H.J.B. Birks and Hilary H. Birks
This book describes the study of past ecosystems, using a variety of methods to reconstruct the past flora and fauna and, by careful inference, the environment. Special emphasis is placed on pollen analysis since pollens are the most abundant organic remains preserved in Quaternary sediments.
Boards £28 304 pages

Plant Taxonomy and Biosystematics
Clive A. Stace
Contemporary Biology Series
A concise and up-to-date view of the theory and practice of present-day plant taxonomy. It emphasises the dynamic, multi-variate nature of the subject which results from taxonomy being both a basic biological discipline and a synthesis of all biological knowledge.
Paper £8.95 256 pages

Circle No. 25 on Reader Enquiry Card.

behaviour, even complex social behaviour. Then these predictions — based ultimately on fitness maximization — can be tested cross-culturally. Thus, the world's human societies constitute a global experiment, with many varying cultures and one constant: our biology. The occurrence of universals such as nepotism and incest avoidance therefore suggests some biological underpinnings. Moreover, if these universals coincide with the predictions of fitness maximization, then social scientists ought to take notice. If biology seems arrogant in seeking to include human behaviour within its view, then what of the greater arrogance of those claiming no such help is needed, or wanted?

As the work of Alexander and others is increasingly showing, much of what human beings actually do accords remarkably well with the prediction of what we expect them to do if they are maximizing their inclusive fitness. But what in turn does this mean? It seems unlikely that we possess genes 'for' discrete cultural phenomena, but equally unlikely that culture and biology are totally uncoupled. Accordingly, new and productive directions may well emerge from current work such as that described in the forthcoming book, *Gene–Culture Evolution* (Harvard University Press), by C. Lumsden and E. O. Wilson.

The real question is not: Does evolution say anything about our behaviour?, rather: How much does it say? Since evolutionary theory is 'right', then human sociobiology cannot possibly be wrong — but it can be misleading. Maybe non-adaptive evolution has had a larger say than most sociobiologists typically assume — maybe fitness is only rarely maximized and optimality theory is just a convenient mythology. Whereas Darwin's message seems indisputable, Hamilton's is less so, although it certainly seems correct. And much of sociobiology (and nearly all of Alexander's work) relies on Hamilton's inclusive fitness theory. Finally, maybe human behaviour is just too dependent on complex non-genetic processes of social learning and cultural experience to be much elucidated by selfish DNA molecules jousting with each other to get ahead. But we owe it to ourselves to find out.

Physicist Jean Perrin once wrote that the goal of science was "to explain the complicated visible by some simple invisible", and Einstein suggested similarly that "the ground aim of all science is to cover the greatest number of empirical facts by logical deductions from the smallest possible number of hypotheses". Our own behaviour is a complicated visible, providing an overwhelming array of empirical facts. Sociobiology employs a simple and powerful invisible (evolution by natural selection), based on a seductively unitary hypothesis (differential reproduction of individuals and their genes). When the wife of the bishop of Worcester first heard of Darwin's scandalous new theory, she is reported to have cried "Descended from monkeys? My dear, let us hope that it isn't true! But if it is true, let us hope that it doesn't become widely known!" By contrast, let us hope that the implications of evolution do become widely studied, for *Homo sapiens* no less than any other species. □

Inspiration for particle physicists

Maurice Jacob

Models of High Energy Processes. By J. C. Polkinghorne. Pp. 131. (Cambridge University Press: 1980.) $24.95, £11.

HIGH energy physics is a fast-moving field, and the paucity of specialized textbooks bears witness to the fact that any detailed exposition of a particular topic runs the risk of becoming rapidly obsolete or of covering a field which drops from the forefront of research. This slim volume cleverly avoids such a predicament. Its discussion of specific techniques will make it a useful tool for many years to come. Indeed, the detailed consideration of how Feynman diagram techniques can be used to obtain asymptotic properties and specific behaviours of model amplitudes covers topics which were of great interest to particle physicists in the 1960s (Regge behaviour) and 1970s (parton model and perturbative quantum chromodynamics) and which are likely to relate to important new developments. The book should be a source of inspiration to the graduate student in theoretical physics and also rewarding to the more knowledgeable reader, for whom it provides access to the wide range of applications of Feynman graph techniques. A combination of heuristic arguments and detailed mathematical treatment makes it easy reading, for reference or as a textbook.

It should be mentioned, however, that, despite its title, this book does not provide a full survey of models of high energy processes. The selective list of topics covered clearly reflects the research interests of the author and his preferred lines of approach. At the same time, many topics are not introduced or discussed as thoroughly as many readers, and in particular students, might wish to see. Mere reference to specialized books will often be inadequate for subjects which are no longer well known to the newcomer, such as Regge behaviour. A more detailed discussion of some topical questions (in particular those involving perturbative QCD) would have been useful to bring the reader fully abreast of present applications. One should, however, mention a detailed presentation of the parton model in a field theoretic language which has recently provoked much interest.

Despite its being too short to meet all requirements, this little book should certainly provide the reader with ideas and with a better understanding of present approaches to high energy interactions. ☐

Maurice Jacob is a senior scientist in the Theoretical Study Division of CERN and a corresponding member of the French Académie des Sciences.

Hypoxia as a way of life

R. D. Harkness

Living without Oxygen: Closed and Open Systems in Hypoxia Tolerance. By Peter W. Hochachka. Pp. 181. (Harvard University Press: 1980.) $17.50, £10.50.

THE thing that strikes you immediately about this book is that the author is an enthusiast. And not simply an enthusiast, but one whose enthusiasm has led him to bring together a great diversity of material to make a coherent story. There is a point in everything he has written, and that, is an unusual achievement for a work that is primarily about biochemistry, a subject prone to accumulation of disconnected facts.

The book is concerned with the ways in which animals obtain energy when they have limited or no access to oxygen. For some this is part of their way of life (intestinal parasitic worms, deep-sea fishes); for others it is a temporary state (fishes wintering in stagnant water, lungfishes sealed in dried mud, bevalve molluscs with their shells shut, seals and other marine mammals when diving). The same sources can provide, for rapid movement, a short-lived burst of energy at a higher rate than could be achieved with the use of oxygen alone (vertebrate and cephaloped muscle). This latter mechanism by degradation of carbohydrate (glycogen) to lactic acid, will be familar to many who would, like myself, be ignorant of other things dealt with in this book. However, the production of lactic acid has snags — its acidity which can adversely affect other tissues. The effect is reduced in diving mammals by use of the acid in organs privileged to have what little oxygen is available, principally the brain and heart (and also, curiously, the adrenals). The problem can also be solved by the production of less awkward end-products, such as by creatures with particular adaptation. One, curiously, is alcohol, produced by goldfish under conditions where little oxygen is available. The fish make ethanol by using in reverse the same set of enzymes as we do to destroy it. how much they enjoy their grog we don't know, but it is nice to think of them quietly solacing themselves as they lie in winter in the mud at the bottom of a cold pond waiting for the spring; and maybe solace others too as they get rid of the alcohol into the surrounding water.

There is much more like this on the curious adaptations which have evolved to enable animals to operate in unusual environments made interesting by the fact that the author is not only a biochemist but also a zoologist. This is what really makes this book so fascinating — he puts the biochemistry into the whole picture of the physiology and life-style of the animals.

So this is a good book which should certainly be in any library that caters for degree students. Is there, then, nothing wrong or the lack of something that would make it better? The approach is primarily biochemical, and the reader needs to be familiar with both the general concepts and the facts of biochemistry. For example, no chemical formulae of compounds are given, only names; enzymes are shortened to abbreviations, explained it is true at the first mention, but not easy to find if you want to check; there is no glossary. Yet the book will interest many who are unfamiliar with biochemical terms, and a short general summary of the biochemical background would be of great value to the non-specialist. To argue that the information is available elsewhere is to miss the point that it is not available when and where it is wanted. Written by Professor Hochachka, at the start of the book, it would not only be in the right place but also probably clearer and more pertinent than anything one could easily find elsewhere.

In one of my excursions into history I came across William Robertson, a most readable 18th century man, who habitually started you off a few hundred, if not thousands, of years earlier. So it would be nice if this book could start in the same sort of way to make it more easily understandable, possibly not to historians, but to a range of people who would find it very interesting but at the moment rather a struggle. So, in summary, an alpha now, and every prospect for an alpha plus for the next edition. ☐

R. D. Harkness is Professor of Physiology at University College London, whose main interest has been in connective tissue with a bias towards comparative physiology.

CALL FOR PAPERS
INTRODUCING THE FIRST RAPID PUBLICATION JOURNAL FOR THE INTERNATIONAL EYE RESEARCH COMMUNITY

CURRENT
EYE
RESEARCH

Monthly
Commencing January 1981

Executive Editors

The principal aim of **Current Eye Research** is to provide rapid publication of full papers, short communications and minireviews, each of high quality.

To ensure rapid publication, accepted articles will be printed directly from camera-ready typescripts prepared by the authors.

Current Eye Research will consider articles encompassing all the areas of eye research. The subject areas include: clinical research, anatomy, physiology, biophysics, biochemistry, pharmacology, developmental biology, microbiology and immunology.

Specially ruled typing sheets and detailed instructions to Authors' can be obtained from either the editors or the publishers.

Clouds in the interstellar medium

B. E. Turner

Giant Molecular Clouds in the Galaxy. Edited by P. M. Solomon and M. G. Edmunds. Pp. 300. (Pergamon: 1980.) £18, $41.

THE distribution and physical properties of the neutral interstellar gas in our galaxy have been major subjects of investigation since the discovery of interstellar atomic hydrogen in 1951. With the discovery 12 years ago of interstellar molecules as a new investigative tool, these studies have been extended to the molecular component with the undertaking of two major surveys of galactic carbon monoxide (CO) in 1975. The present volume is a collection of papers on this and related subjects as they stood in mid-1977 at the Third Gregynog Astrophysics Workshop, held at the University of Wales.

As with much of astrophysics, our perceptions of the interstellar medium vary on a timescale rather short compared with that of the publication of this volume. Even the title suffers as a result. It refers to one of two main topics covered, namely the properties of the molecular cloud ensemble that is generally agreed to comprise by mass at least 75% of the total gas of the galaxy interior to the Sun. The principal question is whether the cloud ensemble is dominated by relatively few 'giant molecular clouds' (GMCs) or by a larger number of smaller clouds. Curiously, the title belies the fact that only one of the two survey groups (Solomon and his collaborators) subscribe to the notion of GMCs, while the other group (Burton and Gordon) find that smaller clouds dominate. Loosely, GMCs may be defined as having masses in excess of 10^5 $M_\odot$ (diameters > 40 pc) as distinct from the many smaller clouds (10^2–10^4 $M_\odot$) seen optically near the Sun. Whether or not GMCs dominate (the question is one of interpretation, not of differences in survey data by the two groups) is important to our understanding of galactic structure, because relatively few GMCs affect the distribution of stars and their motions much more than does the same quantity of gas residing in more numerous, smaller clouds. In the past year, extensive modelling of galactic cloud distributions by Liszt and Burton has shown that the observations are consistent with an ensemble of numerous, smaller clouds with at most only about 4% of the clouds by number being GMCs. Although the title of the book may therefore describe only the minority component, it must be emphasized that GMCs are known observationally, the dozen or so examples being discussed in the first two papers.

Star formation, and its association with molecular clouds, is the other principal topic of this book. Where stars may be directly observed, it has been clear for some time that massive OB stars form in or at the edges of the larger molecular clouds (mass of 10^4 $M_\odot$ or larger) while only low-mass stars (including T Tauris) form in small clouds. Observational examples of each of these cases are given in two papers. Other articles discuss various mechanisms for the onset of massive star formation, such as density wave implosions, sequential formation by O star radiation, supernova inducement, cloud-cloud collisions and so on. Doubts about the applicability of any of these mechanisms to at least one object (CRL961) are discussed by L. Blitz, who contributes much of the observational material in this book not available in the open literature. The probable association of OH and H_2O masers with massive protostellar objects is set forth in three observational papers, and the relation of HII regions and molecular clouds is the topic of two papers. On the theoretical side, magnetic fields (the *bête noire* of any model of star formation) are discussed with originality if inconclusion in two papers.

In addition to the above two topics, this volume includes several articles on peripherally related subjects: some outdated work on the galactic centre (two papers); two works on highly specific aspects of interstellar chemistry (on nitrogen chemistry and interstellar biochemicals — the latter is notably speculative and has appeared in journals several times); and finally, even an entertaining paper on the search for planetary systems.

As might be judged from such a plethora of topics, the book is not intended, nor does it succeed, as a synthesis of any aspect of interstellar clouds. Unfortunately, there are no discussion sessions which might have tied the various viewpoints together; thus the forum of a workshop is not reflected in the book. The introduction by the editors serves as a (rather one-sided) overview, but not more.

The belated publication of this volume has limited the usefulness of much of it; no fewer than 21 of the 31 papers, and parts of some others, have appeared in journals. Nevertheless, some valuable material has not been published elsewhere. Examples are the beautiful colour maps of the Solomon *et al.* CO survey, the large-scale CO maps of the Cygnus X, Taurus and Perseus regions in the paper by Blitz, and several of the theoretical discussions.

The book is handsomely produced on high-quality paper, with fine illustrations and a well-thought-out index. Overall, it is certainly to be recommended as a reference book for institutional libraries, and at the price it may well find a place in the personal collections of serious students of the interstellar medium. It is less suitable for a more general audience. ☐

18 September 1980

Black sheep slink home from Geneva

On the principle that one man's victory is another's defeat, last week's proceedings at Geneva of the second review conference of the Non-Proliferation Treaty (NPT) were not a simple failure. The nuclear powers, it is true, are understandably crestfallen at having failed to persuade their fellow signatories that they have done their best to keep their side of the bargain, especially in strategic disarmament and assistance with civil nuclear technology. But many among the non-nuclear power signatories are correspondingly cock-a-hoop at having stuck to their subversive guns during the Geneva meeting, insisting that the record of the nuclear powers in the past five years does not justify a clean end-of-term report. The non-nuclear powers insisted at Geneva that, if the nuclear powers really wanted a consensus declaration, they would have to agree on the spot to behave as if the Salt II treaty had been ratified, and embark on multilateral negotiations on tactical nuclear weapons and other steps judged unacceptable (see *Nature* 11 September). The failure to reach agreement is also, however, a failure in a broader sense. The signatories of the Non-Proliferation Treaty are loosely held together by a variety of pressures. Some have a genuine conviction that the NPT is a valuable instrument of arms control. Others have been persuaded to sign through coercion by nuclear powers. Others hope that they will have an inside track in nuclear assistance. The most immediate danger now is that this conglomerate of signatories will begin to fall apart. Only a few defections from the treaty (which includes a provision for giving three months' notice) could do a great deal of damage. How likely is such a course of events? What would be the consequences? And what now should the nuclear powers do to make up for the disappointment of Geneva?

Whatever the fall-out, rapid defection is unlikely. Indeed, even the most disaffected signatories will probably stay in the club, at least for the time being. The opportunity to tweak the lions' tails that Geneva provided may after all recur. Political pressures will also persist, as will the tangible threat that withdrawal from the treaty, and from the system of safeguards operated by the IAEA at Vienna, would deprive many states of much-needed nuclear supplies. And a great many signatories will know that they may jeopardize the whole non-proliferation system if they now rock the boat by walking out in a huff. Defections will come, if at all, only much later and for different reasons. No government now a signatory of the NPT is going to embark on the manufacture of nuclear weapons lightly, and without a careful assessment of the political as well as strategic risks of such a step. For most countries interested in such calculations, the political risks of resigning from the NPT are likely to be much smaller than the other risks. Accordingly the failure of the review conference to agree on a final statement cannot be decisive in any present signatory's calculations of the future. The consequences are most likely to be that governments which have so far held out against signing the NPT will now be even more reluctant. In short, the setback at Geneva last week does not, of itself, imply the end of the NPT system as it is.

What the ructions at Geneva do imply, however, is that the non-nuclear powers are much more fierce in their discontent with the past five years' progress in arms control than the nuclear powers had expected. To be sure, the nuclear powers (especially the superpowers) went to Geneva expecting trouble. They expected to be hauled over the coals, told that their performance (and especially their failure to ratify Salt II) was inexcusable and warned that they would have to do much better in the future. In the event, they were not let off the hook as easily as they had expected. Indeed, they were not let off the hook at all. The demand that the signatories of Salt II should behave as if they had ratified it was plainly unacceptable to the Soviet Union. (Although the United States government has often said it would behave as if Salt II had been ratified, President Carter's representatives at Geneva would have been acutely aware that a President Reagan might think differently.) Both superpowers would have shrunk from the demand that Salt III (which is supposed to be concerned with tactical weapons) should be thrown into the Committee on Disarmament, and perhaps with reason.

In a quite dramatic way, however, the NPT review conference has been a psychological shock to the nuclear powers and indirectly to the non-nuclear members of NATO and the Warsaw Pact. Hitherto, it has been possible for the nuclear powers to excuse the slow pace of their arms control negotiations on a variety of grounds — trouble in Afghanistan, uncertainty in the Middle East, presidential elections here or there. What the non-nuclear powers told them at Geneva is that they must make progress whatever the circumstances. This will be a hard prescription to follow. They are, for example, being required seriously to contemplate the completion of the Comprehensive Test-Ban Treaty negotiations and then of giving up all nuclear tests for good (see *Nature* 14 August). The prescription is all the more authoritative because the dissidents at Geneva were not just disaffected developing countries — Sweden and (less openly) countries such as the Netherlands had unkind things to say about the nuclear powers.

How, then, will the black sheep respond? It is tempting to think that Mr Edmund Muskie's statement last week that the US government is now prepared to talk to the Soviet Union about nuclear missiles in Europe is one reaction to what happened at Geneva. Certainly that is a step forward, and one that will bring some good cheer in West Germany as well as elsewhere in Western Europe. But the connection is unfortunately too indirect. There is very little evidence that the Secretary of State has yet had time to consult other interested European states about the form negotiations of this kind should take — yet the European members of NATO are anxious that the next Salt treaty should not be an exclusively Soviet–American deal. Mr Muskie also studiously avoided mentioning the Committee on Disarmament in this context. And he (like everybody else) knows that he will not be able to deliver on his promise if his president is not re-elected. Similarly, the ratification of Salt II must be held up at least until the new Senate assembles in the new year, and may then be just as unlikely as it has been for the past year.

If the nuclear powers seek, as they should, some way of disarming the criticisms they encountered at Geneva on arms control, they have very little choice but to push ahead with the Comprehensive Test-Ban Treaty. The report on these negotiations put out at the end of July was a surprisingly cheerful document, suggesting that much of the technical work has now been done. A little more talking might be enough to do the trick. Indeed, for the past few weeks some of those concerned with the negotiations have been saying that the only missing ingredient in the Comprehensive Test-Ban Treaty is the will of the superpowers to sign on the dotted line. Although plainly an exaggeration (for the Soviet demand that there should be as many remote seismic monitoring sites in the United Kingdom as in the United States remains unresolved), this must be a good approximation to the truth. The question now is whether the drubbing at Geneva will persuade the superpowers to complete the treaty.

The chances are slim. The political inhibitions of the past few months persist. In the circumstances, the nuclear powers should think of taking more seriously the persistent demand of the non-aligned signatories at Geneva — that more of the process of arms control should be entrusted to the Committee on Disarmament in Geneva. It is entirely understandable that the committee has earned itself a bad reputation. For the first decade or so it was a talking shop for the rehearsal of idealistic but also unrealistic schemes for disarmament. Pilloried at regular intervals, the superpowers took care to avoid trouble (and to nullify the committee's work) by the device of their control of the chairmanship of the committee. Since the reorganization (and enlargement) of the committee five years ago, however, its proceedings have been more temperate and more valuable. Moreover, the committee has the virtue of being the only forum of its kind in which both France and China are represented. Because at some stage neither the existing Partial Test-Ban Treaty nor the putative Comprehensive Test-Ban Treaty can survive indefinitely if France and China stay outside, the nuclear powers have everything to gain if questions of French and Chinese adherence to these schemes are seriously taken up. What is needed is a definition of the circumstances in which France and China would sign. The old device of cutting off other people's military production of nuclear explosives is unlikely now to be sufficient. The Geneva black sheep might at least find they were not the only animals of that colour if they used the Committee on Disarmament as a means of exploring such questions.

The nuclear powers have not merely to meet criticisms that they have dragged their feet on strategic arms control (Article VI of the NPT) but also that they have fallen short of their obligations to help with the spread of civil nuclear technology. Here, by good luck, they have an early opportunity to disarm their critics. At the end of this month, the IAEA Committee on Assurance of Supply will meet for the first time in Vienna, chiefly to discover which members of the IAEA have chosen to belong (it is a free-for-all) and to decide when to meet next. Potentially, however, the committee is a means by which the nuclear suppliers (not all of them nuclear powers) could help meet the just criticisms that have arisen of their supply practices. As things are, many governments fear that, after building a nuclear reactor, they may be unable to buy fuel for it on the world market. Only last week, the US Congress finally overrode President Carter's wish to send a consignment of enriched uranium to India; the uranium is contracted for on both sides, but prohibited by the Anti-Proliferation Act of 1968. South Africa is in similar difficulties. Nobody would quarrel with the objectives of this act, which are to require that states supplied with nuclear materials from the United States should agree that all their nuclear installations are covered by IAEA safeguards. The trouble is that the act has demonstrated to all and sundry that arbitrary legislation can always interrupt supply. The result has been to damage confidence. The Anti-Proliferation Act should be repealed, but the IAEA meeting later this month should be used as a means of rebuilding confidence, if necessary by enabling the IAEA itself to become a supplier of nuclear fuel (as its existing statutes allow).

Dismal science in doghouse once more

Economists have often been derided for failing to agree among themselves on the future performance of this or that economy. Now they are in deeper trouble, and are being blamed for having misled the British government. Mrs Thatcher finds herself in serious political difficulties because it now seems that nobody has any clear idea of how much money there is at present in the British economy, or how quickly this money stock is increasing. The issue is important because the government has built its economic policy on an attempt to control both the rate at which the money stock increases and the rate at which the government itself borrows from the public. What has gone wrong?

Part of the difficulty is that the notion of what constitutes the money stock is, to say the least, abstract. It includes not merely the nominal value of the currency in circulation but also the value of borrowing from the commercial banks. This extension of the simplest concept of money makes sense for, in a modern state, bank money far outweighs currency in numerical terms. It is beyond dispute that the money supply is a valuable indicator of economic trends. Broadly speaking, the less money, the less there is to spend on consumption, investment or both. Moreover, governments (or their central banks) can hope to influence money supply by adjusting the interest rate at which they lend to commercial bankers. Monetarists and their critics differ only in their assessments of the importance of this instrument of monetary policy.

The Thatcher government, consistently (to its credit) but some say wrongly, has tried since its election in May last year to follow monetarist policies. In this spirit, it has kept interest rates high, and has tried to cut its own spending. It has been more successful at the first task than at the second — or so it seemed until the money stock was seen to have jumped by five per cent in July and a further three per cent in August.

The reasons for the sudden jump in the British money supply are linked simply with the abolition (in June) of a system whereby the Bank of England sought, two years ago, to limit the growth of money (currency and bank credit combined) by restricting the rate at which individual banks could increase lending. People seeking credit were forced at some cost to go to commercial companies which are not banks and also to banks abroad. Now that the restrictions have been abolished, this informal lending has returned to the banking system, and the money supply has dramatically increased, causing widespread confusion and alarm. It remains to be seen whether the British government will be diverted from its present course by all the fuss, although the British Treasury last week was claiming that nothing had gone wrong, and that the "underlying" growth of the money supply was not excessive.

The Treasury may be right, but should know better than to peddle such facile nostrums. The money supply, although easily defined, is not easily measured. Bank money can be measured simply, but this is not the whole story. If, for example, a manufacturer persuades a supplier to give him an extra month to pay his bills, the money stock has been increased by that amount just as surely as if the manufacturer had borrowed from the bank. So the Bank of England's estimate is that attempts to control the money supply (as measured) will provoke a kind of monetary equivalent of Le Chatelier's principle — there will be compensating (but smaller) adjustments in the opposite direction.

Economists at the Treasury (and their academic colleagues) can be blamed for not having made this much crystal clear to the government, to politicians and to the public. Collectively they must also wear a hairshirt for having failed to emphasize that the control of the money supply is not an end in itself, but rather an index of how monetary policy as a whole is working. The British government's chief objective is to reduce the rate of inflation, to which end high interest rates (and reduced public expenditure) must surely contribute. A fall in money supply would indicate that inflationary pressures are abating. The converse is not however valid, as the past few months have shown. So there is every reason for the British government (if it has the nerve) to stick to its present policies, but with a more intelligent view of what the economic indicators mean. The most urgent need is, however, for a more intelligent (and effective) means of controlling public expenditure. Much of the British government's "saving" so far consists of the requirement that nationalized industries such as the telecommunications network should raise the capital they need for expansion from current users. The consequences are absurd — and inflationary to boot.

0028-0836/80/380178-02$01.00

understand the hazard". The document also criticizes as unwarranted Professor McCarthy's inferences about the production of aerosol particles carrying virus from safety cabinets used in the smallpox laboratory.

Those questioned earlier this week about the ASTMS allegations were unwilling to comment without an opportunity to study the text. Those witnesses at the court hearing who were reached by telephone said, however, that they stood by their evidence.

The coroner at the inquest on Mrs Parker's death had let it be known in advance that he did not wish to go over ground already covered at the court hearing. Mr Clive Jenkins, General Secretary of ASTMS, has nevertheless written to him with a copy of the document. He has also written to Dr Gerald Vaughan, Minister of Health, demanding that the Dangerous Pathogens Advisory Group be reconstituted by including public interest and trades union representatives, and that the government should make clear that it is prepared to spend the monies necessary to make laboratories in universities and hospital pathology departments safe.

Law of the Sea

Hurdles to jump

Washington

Final agreement on international legislation covering deep-sea mining could prove more elusive than suggested by the successful completion of negotiations on a draft United Nations Law of the Sea Treaty in Geneva last month. Even if — as indeed seems likely — a draft treaty is finally agreed and signed by member nations after a final meeting in Caracas early next year, there remains the question of ratification, required of at least sixty states. And this could prove a major stumbling block, particularly in the US Senate.

Member companies and trade associations of the American Mining Congress (AMC) are meeting in San Francisco next weekend to decide their position on the draft treaty which emerged from the Geneva negotiations, the culmination of more than twenty years of talks.

Prior to the Geneva meeting, the congress had expressed strong reservations about some aspects of the US negotiating position, claiming that the chief US negotiator, Ambassador Elliott Richardson, was giving away too much in his eagerness to get the treaty signed.

Many of the companies still express the same reservations. And the AMC's views could be crucial in determining whether the US Congress decides to back the treaty. Earlier this year, following strong pressure from the mining companies, Congress passed a unilateral law defining conditions under which US companies could engage experimentally in deep-sea mining from 1981 unless the UN treaty is in force. Similar actions by Germany, and proposed actions by the United Kingdom and France, are among the factors said to have precipitated the Geneva agreement.

The stakes are high. Total investments of more than $1,000 million are expected to be made by each of the four major consortia now preparing to engage in deep-sea mining, primarily for manganese nodules containing nickel, cobalt and copper. The companies are demanding, above all, a degree of certainty about a reasonable return on their investment.

Among the areas that the mining companies are unhappy about are:

- The lack of guaranteed representation of the United States on the 37-member council of the International Seabed Authority, even though the Soviet Union is given three seats, a position which one executive predicted that the Senate would find difficult to accept.
- The participation as signatories of the treaty of organizations other than UN member states, such as the Palestine Liberation Organization. This could entitle such organizations to share in the profits of deep-sea mining which the US companies are required to provide to the authority for distribution as development aid.
- The requirement that mining companies should make their mining technology available to other countries who demand it.

The major question now facing both US and UN negotiators is whether any movement is possible on these issues before the treaty is signed next year and, if not, whether they are likely to provide a sufficient obstacle to prevent Senate ratification, given the many other advantages to the United States in an international treaty that covers all aspects of nations' rights to the oceans.

None of these reservations is, in itself, expected to be a major stumbling block to the final treaty. Nor, among those who are strong supporters of the treaty, is there any desire to open up discussion again in case the whole package begins to unravel. But claims that "it is all over bar the shouting" may turn out to be a little premature.

David Dickson

Overseas students

Some win, some lose

British universities and colleges appeai to differ markedly in their expectations of numbers of overseas students in the coming academic year. Some universities — a litte to their surprise — expect there will be very little change between last year and this in the numbers of students from overseas. Others expect that numbers will be, by contrast, substantially reduced.

The issue has become a lively topic of conversation among academic registrars because the coming academic year is the first in which the steep increases of student fees decreed by the British government a year ago will begin to bite. The fees apply only to new students, or to students embarking on new courses. Registrars are also quick to point out that at this stage in the academic year, before students have actually registered and paid their fees, estimates of how many will turn up are bound to be provisional.

The universities where there appears to have been very little change in the demand for places include the University of Salford and Loughborough University of Technology. At both institutions (as at most universities) overseas students are now required to produce not merely their fees but a financial guarantee from a bank or some scholarship awarding body, which may require that a student should have £6,500 at his disposal in each of three consecutive academic years.

Elsewhere, the preliminary figures suggest that some kinds of courses are likely to suffer more than others. Applications for places on MSc courses appear to be comparable with last year's at some institutions, which are nevertheless guessing that overseas students will be reduced by ten per cent or more in undergraduate and PhD courses.

One of the difficulties of estimation is that students who have nominally accepted places fail to turn up by the beginning of term, for most British universities early in October. In normal years, it is expected that overseas students will apply to several universities but in the end accept a place at only one of them, which means that a certain amount of double counting is unavoidable at this stage in the academic year. But some also fail to turn up for reasons which are never explained. Some registrars fear that difficulties over finance may increase the numbers in this category in the coming year.

With all these reservations, Imperial College, London says that there has been a "discernible" reduction of the numbers of completed applications from overseas. Portsmouth Polytechnic, one of the largest institutions of higher education in the United Kingdom, is similarly affected — and wonders ruefully whether the explanation may not be the rules which require polytechnics to charge fees laid down by the Department of Education and Science. This year, polytechnic fees for overseas students are nominally some £300 to £400 greater than those in universities.

While registrars at all kinds of institutions agree that the present period is more confusing than any other within living memory, most of them appear to be mildly encouraged that the decline in numbers has not been as dramatic as some of them were fearing earlier this year. Unless there is a sharp deterioration in the next few weeks, overseas student numbers are unlikely to be reduced by anything like the 50 per cent feared by some or by the 30 per cent which appears to have been the base-line for financial planning for the coming year.

CORRESPONDENCE

Pay as you go

Sir—Although far more interesting and important things are now happening in Poland, let me bring to your attention one more Polish subject connected with the Polish regime's abuses of decency or simply the law. Every Polish scientist going abroad for professional purposes, and for a long period, is forced to sign a declaration. ("Long period" means more than eleven weeks. Why just eleven? — Nobody knows.)

The declaration is an obligation to pay some arbitrarily fixed sum of money every month to the so-called "hard currency scholarship fund", created apparently to finance foreign trips for some unspecified persons. The point is that although many Polish scientists were forced to, and did, pay their money *to* the fund, no-one has ever heard of anyone actually getting something *from* this fund. There are rumours that the money is being used to finance "study" trips for Polish journalsts, for example to the United States, where they use the American money to collect materials for painting the American system in black colours. Indeed, the fund in question is under no form of public control, and no-one really knows to what purpose the money is used. The character of the deal comes out most clearly from this paragraph in the declaration:

> "If the currency regulations of the country where I shall be staying would make it impossible to send my contribution to the hard-currency scholarship fund via a bank, I undertake to send the remittance to the nearest agency of the Polish People's Republic abroad."

As you are aware of the political situation in Poland I hope that you will understand my request to keep my name, and address a secret.

Name and address *withheld* — Ed, *Nature*

Nuclear power costs

Sir— The Central Electricity Generating Board (CEGB) is to be congratulated on providing more details of its cost comparisons for the different power station types. As it emphasizes in its report, current relative economic performance of coal and nuclear systems is not an adequate guide to future investment decisions. However, one could argue that operating experience is a guide to future technical (rather than economic) performance. Load factors are one measure of technical performance, and your report made some pertinent observations regarding the reported load factors of power stations operated and planned by the CEGB (*Nature* 21 August, p.753). Obviously the cost per kWh per annum is sensitive to the load factor and it is informative to recalculate the predicted generating costs of possible future nuclear and coal power stations using load factors consistent with those quoted for existing stations. The table summarizes factors on design output given in the CEGB report load.

	Nuclear	*Coal*
Stations (1965–77)	56%	61%
Hinkley B; Drax I	43%	73%
Stations under construction	49%	56%
Future stations	63%	54%

The figures show an unexplained optimism for nuclear systems and a corresponding pessimism for coal systems. Assuming load factors consistent with experience (say 70% for coal and 50% for nuclear) reverses and predicted cost ranking for the fuels in question. Specifically, nuclear comes out some 8% more expensive than coal (2.8 p per kWh compared with 2.6 p per kWh) rather than 35% cheaper as derived by the CEGB.

Why examine?

Sir—It was interesting to read the article on school examinations (*Nature* 3 July p.2). As one who, although born and educated in the United Kingdom, has spent most of my working life teaching overseas, my usual plaint is that the schools we have to deal with do not teach A levels and that it is so much better in the UK where they do. The main reason why the schools I know do not teach A levels is not choice, but simply lack of qualified teachers.

As in everything else, there are pros and cons and things look different from the other side of the fence. One thing I am convinced of, however, is that good schools are much better at teaching A-level material than are universities. In general, university staff do not make good school teachers.

Third World matters

Sir—"Pesticides in developing countries" (*Nature* 28 August p.832) was a patronizing editorial on the *New Internationalist*; a journal that is not a "citadel for extreme environmentalists" but a medium for exposing injustice, stimulating debate and campaigning for and on behalf of the poor of the Third World.

Transnational corporations are mostly the villains because it is often their trading practices that accentuate North–South differences. Global profit maximization policies tend not to be compatible with the needs of the people of the Third World. For example, infant mortality rates have increased significantly in areas where advertising has persuaded mothers to abandon breast feeding for Nestle milk powder products. Other cases are more insidious: uncontrolled marketing of harmful products, including cigarettes and pesticides. High blood levels of DDT (30 x that in USA) being the corollary of one aggressive marketing campaign in Guatemala.

New Internationalist is not a scientific journal. It does try to report facts accurately and from an objective stance. This is expected of *Nature*. It was unfortunate that a basic, scientific definition had to be distorted in order to accommodate editorial views: DDT *is* a poison, a poison being a substance that when introduced into or absorbed by a living organism (or ecosystem) destroys life or injures health.

May I reiterate Clive Jenkins' final point (*Nature* 21 August p.754) that *Nature* should abandon prejudice and support quite reasonable crusades to protect people.

Felig replies

Sir,— Your account of the events surrounding my resignation from Columbia University (*Nature*, 21 August) contains a number of inaccuracies and omissions which may lead the reader to a distorted view of this unfortunate affair.

Firstly, my proposal that Dr Soman be considered for a faculty appointment at Columbia occurred in January rather than February 1980, *before* the first audit which revealed data falsification by Dr Soman. Secondly, the letter by Soman in February 1980, declaring his responsibility for the similarities to the paper from the Roth laboratory and for "fudging" data, was not written at my request but was his own effort to "set the record straight" at the time of his resignation. Dr Soman had, in fact, admitted in March 1979 that he had retained a copy of the Wachslicht–Rodbard manuscript and had used parts of it to prepare his own manuscript. At that time he was severely reprimanded and steps were taken to assure Roth's priority.

Thirdly, the delay in obtaining the first audit was a result of the failure of the agreed upon auditor (Dr Edward Rall) to follow through with his offer to come to Yale and review the original data. Fourthly, while Dr Roth is quoted as considering it "careless" for us to allow publication of our paper pending an audit, he had in fact written to us on 5 March 1979 that "I hope you will go on to have your fine and original piece of research published appropriately". Fifthly, those papers which were considered questionable after the second audit involved studies for which original data were not available for audit because Dr Soman (by his written admission) had destroyed the original notebooks. Sixthly, in addition to informing Dean Tapley on 27 February 1980, I met with five of the senior faculty in the Department of Medicine at Columbia in May 1980, prior to my assuming the Chairmanship, and informed them of Soman's data falsification and that I would be sending letters of retraction to journals.

Finally, your article fails to take note of the fact that at the time the paper on anorexia nervosa was submitted for publication by Soman and myself, Soman was in his third year of a faculty appointment at Yale, had extensive independent grant support, was responsible for his own laboratory and was highly regarded by all his colleagues. Any retrospective analysis of the handling of his wrongdoing in using the Wachslicht–Rodbard manuscript to prepare his own must be viewed in that context.

injury. Therefore we are also convinced that we must possess an isolated private alarm system which inevitably links injury to pain. The failure of this concept to explain the observed clinical and experimental facts has been discussed extensively and led to the gate control theory[33] and its extensions[34]. Chung and Dickenson use gate theory[33] as though it applied only to a 'pain system'. An acceptable pain theory would have to incorporate an explanation of at least the following clinical facts: (1) the bizarre coupling of the amount of injury to the amount of pain, (2) the triggering of pain by innocuous stimuli to normal tissue (tenderness, referred pain and trigeminal neuralgia), (3) the sensation of pain in missing limbs, (phantom pain), (4) the failure of narcotics to influence some pains, (brachial plexus avulsions), (5) the success and failure of the various counter-stimulation methods (acupuncture, transcutaneous stimulation).

Undoubtedly for lack of space Chung and Dickenson have concentrated on only one particular 'pain' inhibitory system, which is said to operate via noxious inputs and the nucleus raphe magnus to modify the activity of spinal cord nociceptive cells. However, as Chung and Dickenson point out this is only one example of many such inhibitory systems[35]. The brain has many reasons, tactics and strategies for selecting and modifying the incoming information it receives. Each of the different neural systems responsible for such 'controls' offers explanations for particular pain states, and opportunities for therapy. Some of the control systems are located in the spinal cord. For example, stimulation of large low threshold sensory fibres produces a striking inhibition of the response of spinal cord cells to peripheral injury[36]. Other control systems act via the brain[37] and there is good reason to suspect that some of these inhibitory effects are mediated by the small cells of the substantia gelatinosa[38]. Therefore the activity of all nociceptive cells is controlled by a balance of excitatory and inhibitory mechanisms mediated by many neural circuits, some local within the spinal cord and some with long arcs extending from cord to brain.

Experimental investigations of the functional profiles of neurones responding to noxious inputs and of their 'controlling' influences have been performed either in isolated parts of the nervous system such as the spinal cord or in highly unphysiological preparations such as anaesthetized or decerebrate animals. These experimental preparations represent a study of the nervous system locked at one extreme of its functional repertoire. While defining limits is a responsible scientific pusuit, it is difficult to establish the validity of these data in speculating about the operation of the system in the behaving organism. Having studied the functional reportoire of cells in these artificial states, it is clearly necessary to return to a study of their behaviour in the intact behaving organism before we can label cells as 'pain' cells. We are a long way from that step. How best to approach it? One way is to return to the animal and human patient to define the input-output nature of their problems rather than to force them to conform with ancient theory of how they ought to behave. We are emerging from a necessary era of physiology in which attention was concentrated on sudden stimuli and the consequent surge of impulses which ran through the nervous system over the subsequent 100 milliseconds. These volleys are travelling over neural circuits whose transmitting qualities have been set by much slower processes. These began in the embryo and obviously depend on a relatively fixed anatomy but it is now becoming apparent that there are also plastic physiological and biochemical processes which shape the responsiveness of nerve cells. It may well be that the huge newly discovered family of peptides including the enkephalins and endorphins have more to do with setting the mode of operation of the nervous system's analysis mechanisms than with the incoming messages which are to be analysed. □

Chung and Dickenson comment: There are two separate issues concerning acupuncture. First, we must ask if acupuncture analgesia is a reproducible phenomenon that can be studied in the laboratory. This question can be evaluated as we have done[1], from published studies. Second, we must ask if acupuncture is clinically effective. This is more difficult to assess, as there are numerous claims and counter-claims and the arguments are generally construed by carefully selecting one set of reports from the 'western experts' and dismissing the results which do not conform with preconceived opinions. We feel that controversy at present over the validity of clinical data is unproductive. Except for a brief mention that stimulation described by the experimenters as 'acupuncture-like' (as distinct from transcutaneous electrical stimulation) appears to be especially effective in relieving chronic pain in man[2-5], we avoided this issue in our review. There are however, many studies demonstrating that electroacupuncture and similar manoeuvres in animals enhance the threshold to pain and influence the responsiveness of pain cells. For example, cells responding steadily to painful stimuli are silenced when "acupuncture-like electrical stimuli" are delivered elsewhere on the body[6]. How the reduced activity of these cells is related to the subjective intensity of pain is unknown, as are the precise neural mechanisms by which such an inhibitory influence is brought about. Regardless of its ultimate clinical usefulness, the phenomenon deserves further investigation, and much of the current research into pain is indeed aimed at elucidating the mechanisms mediating inhibitory influences.

As Wall and Woolf point out, the involvement of opioids in modulating pain is not fully understood and conflicting evidence exists. It is likely that the role of opiates or endogenous peptides in the perception of pain will turn out to be complex. Of the many levels of the central nervous system at which pain transmission can be modulated, the raphe-spinal system appears to exert the most powerful inhibitory effects. We concentrated on this system mainly because the evidence for its inhibitory role is least controversial. Opiates[7], central electrical stimulation[8,9], acupuncture[10] and, more recently, transcutaneous nerve stimulation[11] have been claimed to act to some extent via this nucleus in producing their analgesic effects.

We have not stated, nor implied, that the pain system is isolated from "feelings and behaviour" or from other sensory systems. There are chains of cells which respond preferentially, and often solely and exclusively, to what the experimenter would consider to be noxious stimuli. These are usually referred to as 'cells which are involved in transmitting nociceptive messages', but to avoid circumlocution, we called them 'pain cells'. □

NEWS AND VIEWS

What we don't know about pain

from P. D. Wall and C. J. Woolf

A RECENT article in these columns[1] by Chung and Dickenson discusses the relationship between pain, the enkephalins and acupuncture. We are told that "placing a single needle into a certain point of the body can produce . . . a potent amelioration of pain". It is proposed that acupuncture analgesia acts by the release of endogenous opioids within the brain and that these enkephalins indirectly stop "pain cells" in the spinal cord from transmitting their messages. How one wishes all this were true. If it were so, we would be well on our way to understanding and controlling the chronic pain states which continue to plague so many. We would like to supplement Chung and Dickenson by examining whether acupuncture does produce pain relief, what evidence there is for a role for the endogenous opiods in modifying nociceptive transmission and how the nervous system is organized to transmit and process information about noxious stimuli.

After 2,000 years of continuous use in China and some 350 years of intermittent Western enthusiasm, we still await controlled clinical trials which conclude that acupuncture is effective in treating chronic pain[2]. Innumerable, uncontrolled and anecdotal reports exist[3]. Such 'trials' report success rates of up to 94%[4] but in a controlled trial at the University of Washington Pain Clinic[5], none of a 100 patients showed any objective benefit after three weeks of acupuncture therapy. Another controlled trial found that acupuncture does produce a very transient analgesia, but that this analgesia occurs equally with 'sham-acupuncture' and with needling of the traditional meridian points[6]. For acute pain, we read of the successful application in China of acupuncture in half a million operations[7], but this does not match the experience of an invited team of western experts[2,8], who witnessed operations on highly selected patients, only a small fraction of whom had pain free operations with needles alone. Moreover the use of acupuncture for surgery in China is reported to be steadily declining[2,9]. There is no doubt that powerful analgesia with acupuncture does occur and has to be explained. Unfortunately, it is a rare phenomenon and for the huge majority of patients the needle is a blunt tool. Evidently acupuncture, when it works, acts by some mechanism which does not always operate in the majority of people, unlike the uniform ability to react to narcotic analgesics.

All sensory stimuli interact with each other producing distraction, jamming and specific local and distant interactions. Many have selected special examples of this general phenomenon and called them 'experimental acupuncture' although they usually bore no relationship to traditional acupuncture practice. In healthy volunteers, needling or electrical stimulation can produce a mild rise in the threshold for certain painful stimuli[10,11]. This antinociceptive effect is most marked in the region of the painful stimulus[13] and not at a distance or at 'meridians' as predicted by classical acupuncture. The analgesia produced by such experimental acupuncture is quite feeble and unlikely to be clinically useful, and must not be confused with the rare cases of perfect surgical analgesia produced by acupuncture or with the use of segmental transcutaneous electrical stimuli which have a highly satisfactory effect on certain types of hyperalgesias[12-14] with minimal effects on cutaneous pain thresholds[15].

There is no doubt that the enkephalins and a number of other opioid peptides are highly concentrated in specific regions within the brain and spinal cord[16], but their role, if any, in pain remains an enigma. One attempt to study this problem has been to investigate the effect of naloxone, an opiate receptor antagonist, on a variety of different pain states and analgesic procedures. Naloxone completely reverses the analgesic effects of administered narcotics[17]. If the endogenous opioids were active in normal men or animals one would expect that naloxone would antagonize their action and consequently produce pain or a drop in pain thresholds. Most studies in man have shown that naloxone has no effect[18,19], while in animals naloxone has been found to produce hyperalgesia[20,21], analgesia[22], and no change[23], in the response to noxious stimuli. Patients suffering from chronic pain are unaffected by naloxone although one might expect these patients to be mobilizing whatever anti-pain resources they possess[24].

Naloxone has been reported to produce a partial reduction both of experimental acupuncture analgesia in man[25], and of the analgesia produced by midbrain electrical stimulation[26], but these results need to be confirmed since conflicting reports are found in animal studies[27,28]. There is evidence in the rat that local segmental interactions between sensory inputs in the spinal cord are modified by naloxone[29,30] but it will be difficult to determine whether similar changes occur in man. Recently, in fascinating but highly controversial work, Levine & Fields[31] report that very high doses of naloxone abolish the placebo reaction, suggesting that the 'analgesia' resulting from blank injections may be produced by the mobilization of endogenous opioids.

Whatever function the opioids do perform in pain, it is unlikely to be simple as indicated by the growing list of endogenous peptide compounds with opioid activity and the subdivision of the opiate receptors into numerous functional categories. One of the problems in interpreting studies using naloxone is that it has a greater affinity for some classes of opiate receptors than for others[32]. Nevertheless it is clear that there is no evidence for an internal narcotic dispensing system in the brain automatically controlling the intensity of perceived pain.

In their summary of the anatomy and physiology of the pathways which bring news of injury to the brain, Chung and Dickenson use the most classical model for simplicity and brevity. They refer to pain fibres and pain cells in peripheral nerves and spinal cord as though there is a specialised chain of nerve cells which leads inevitably from the fact of injury to the sensory experience of pain. They further isolate this 'pain system' by saying that "in stark contrast to the other senses it is characterised by elaborate feedback networks" which "ensure that it is fail-safe" and "which, when activated, reduces the intensity of persistent pain". This approach "which implies a distinct anatomical and physiological pain system separate from other sensory systems" represents a definite philosophy which would shape future experiments and have considerable therapeutic implications if true. For example, given a distinct anatomy such as the pain cells described and a distinct feed back control such as the raphe nucleus and distinct chemistry such as the enkephalins, one might reasonably hope to achieve pain control with no influence on other aspects of feeling or behaviour. The concept of a separate pain system originates in our own introspective certainty that pain itself is a clearly discrete category of experience which we are convinced implies

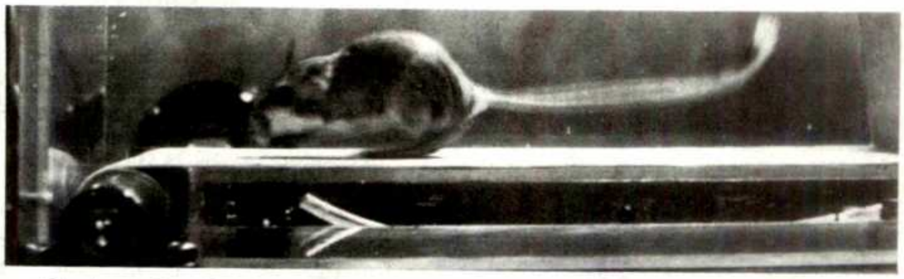
Hopping and running on two legs or four

from R. McNeill Alexander



Dipodomys deserti hopping on a moving belt to assess energy consumption. Experimental details are given by Thompson *et al.* on p.223 of this issue of *Nature*.

MOST mammals run on all fours but some run on just two legs (like men) or hop (like kangaroos). Some birds run, some hop and some do both. What are the relative merits of the different gaits? Do they differ in energy cost?

Energy costs of running and hopping can be inferred from measurements of oxygen consumption. Some of the difficulties of physiological experimentation on moving animals can be avoided by training the animal to run on a moving belt as shown. Data has been collected for mammals ranging from mice to horses and lions, and for many birds (summarized by Fedak & Seeherman *Nature* **282**, 713; 1979). Nearly all of it conforms to a simple rule: the power P required for level running at speed u is given by

$$P(u) = P(0) + ku \qquad (1)$$

where k is a constant for the particular animal. $P(0)$ is a little more than the power consumption at rest because it includes a component for maintenance of posture.

Equation (1) implies that the energy required to travel a given distance (in excess of the requirement for standing still) is more or less independent of speed.

This may seem remarkable, but experiments with red kangaroos gave an even more remarkable result (Dawson & Taylor *Nature* **246**, 313; 1973). The power consumption of a hopping kangaroo is independent of speed, or may even fall slightly as speed increases. The energy used by a kangaroo travelling a given distance therefore falls steeply as speed increases. At low speeds a kangaroo uses far more power than (for instance) a gazelle of the same mass, but at 5 m s^{-1} the two animals use about equal powers. It has been suggested that at higher speeds, a kangaroo might travel more economically than a gazelle, but it is difficult to measure power consumption at high speeds because the animals build up oxygen debts.

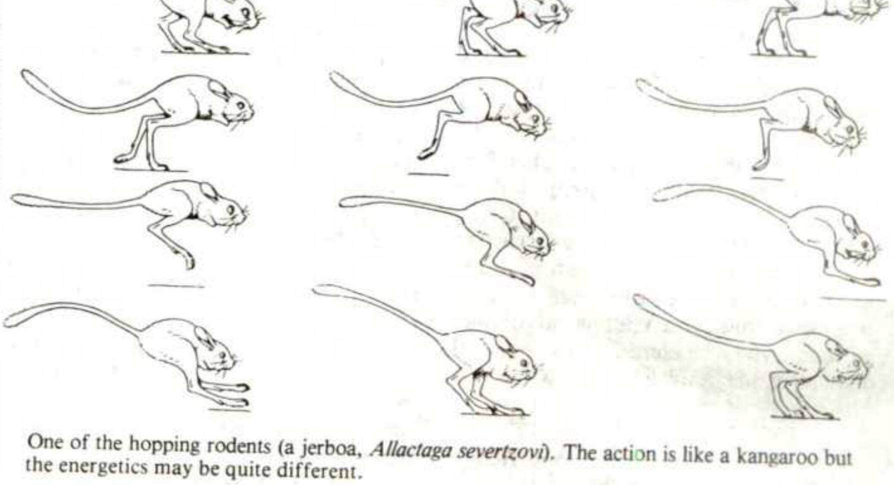
Various rodents hop like small kangaroos. There are kangaroo rats (*Dipodomys*) in N. America, springhares (*Pedetes*) in Africa and hopping mice (*Notomys*) in Australia. Is power independent of speed for them all? Thompson, McMillen, Burke & Taylor (this issue of *Nature*, p223) find that it is not. Equation (1) holds for many and probably all hopping rodents, with values of k about the same as for quadrupeds of similar mass. The same is true for the rat kangaroo (*Bettongia*, a marsupial). The large kangaroos seem to stand alone in their peculiar energetics.

Though equation (1) holds for a wide variety of animals, the constant k is different for animals of different sizes. Until recently the data seemed to indicate that k was proportional to (body mass)$^{0.6}$ for quadrupeds but to (body mass)$^{0.8}$ for bipeds. Consequently bipedalism was more economical than quadrupedalism for small animals, but less economical for large ones. Why, then, are there small quadrupeds (such as mice) and large bipeds (such as ostriches and, formerly, tyrannosaurs)?

This apparent paradox seems to have been an artefact of the sample of species originally selected for study. Fedak & Seeherman (*Nature* **282**, 713; 1979) showed that though penguins and geese need twice as much power for running as dogs of the same mass, ostriches are as economical as ponies. For any body mass, a wide range of values of k is possible, but the general trend both for quadrupeds and for bipeds is for k to be proportional to (body mass)$^{0.7}$.

It would be satisfying to be able to explain why kangaroos and smaller hoppers have different relationships between power and speed, and why k tends to be proportional to (body mass)$^{0.7}$. This has not yet been achieved. Calculations based on the mechanical work required of the leg muscles provide satisfactory explanations of the power requirements of kangaroos and also of quadrupedal mammals of similar size, and show that slow hopping is more expensive than running because it involves larger fluctuations of potential energy (Alexander & Goldspink *Mechanics and energetics of animal locomotion*, 1977).

Similar calculations grossly underestimate the power requirements of small runners and hoppers, such as mice and quail: indeed they predict that k should be proportional to (body mass)$^{1.0}$. Taylor, Heglund, McMahon & Looney (*J. exp. Biol.* **86**, 9; 1980) have recently tried to resolve this discrepancy, by suggesting that the main metabolic energy cost of running is associated with the generation of muscular force, rather than the performance of work. The forces required are proportional to body mass but smaller mammals need faster muscles, with shorter cross-bridge cycling times, so exertion of force may be more expensive for them. Taylor and his colleagues show for rats, dogs, men and horses, that carrying a load increases k in the same proportion as it increases the forces on the feet. This is consistent with their hypothesis but is not clear evidence for it (as they themselves admit), because the experiment increases forces and work in the same proportion. The hypothesis is unlikely to win general acceptance unless it can be supported by less ambiguous evidence and shown to be quantitatively consistent with our knowledge of muscle physiology. □



One of the hopping rodents (a jerboa, *Allactaga severtzovi*). The action is like a kangaroo but the energetics may be quite different.

from *How mammals run* Keter Publishing House, Jerusalem, 1974.

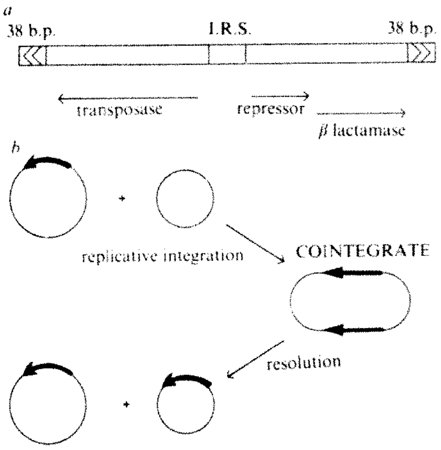
Movable genes

from Ron McKay

BARBARA McClintock's early studies on the breakage- fusion bridge cycle in maize served for many years as a reminder that a major class of genetic change was not explained by the central theories. This year's Cold Spring Harbor Symposium (May 28 — June 4, 1980) showed quite clearly that genetic instability now occupies a central place in our understanding of both heredity and development. The recent rekindling of interest in this field stemmed from observations of the rapid spread of drug resistance markers in bacteria but now extends to eukaryote molecular genetics. In prokaryotes it is clear that there is a class of DNA which promotes its own rapid spread within and between bacterial species. The physical structure of these mobile genetic elements is well understood and current goals are to determine the mechanism and enzymology of this genetic exchange.

One of the best understood of the mobile elements is the bacterial transposon Tn*3*. Transposon Tn*3* confers resistance to the antibiotic ampicillin as it carries a gene which specifies the ampicillin degrading enzyme ß-lactamase. The studies of Heffron, Casadaban and others have shown that as well as this genetic marker Tn*3* carries two genes which function in trans to promote genetic movement or transposition (Fig. *a*). After transposition a new copy of Tn*3* is found at a new integration site but the old copy is still found at the original site — a key feature which distinguishes the movement of transposons from the integration-excision system found in bacteriophage lambda. However, as with phage lambda, transposable elements require certain DNA sequences in cis for transposition. These sequences fall within the inverted terminal repeated sequence which is found at the ends of all mobile genetic elements. The process by which a new copy of a transposable element coding for its own transposase is inserted into another replicon is thought to occur via a fused structure called a co-integrate in which two copies of the transposable element flank the donor molecule (Fig. *b*). Cointegrates from transposons known to code for their own transposases (Tn*3* and Tn*5*) have only been found using mutant transposons. Normally no cointegrates are seen but in some mutations all the transposons are cointegrates. Therefore cointegrates have been proposed as intermediates in transposition. Other transposons which have not been shown to code for transposases but which have IS*1* elements at their ends (for example, Tn*9*) give rise to cointegrates as the end product of wild type transposition. The fused replicon can be resolved, as shown in Fig. *b*, to give the two starting replicons with an additional copy of the transposable function. Heffron (University of California, San Francisco) has shown that the resolution of co-integrates also requires a DNA sequence within Tn*3* in cis. This sequence falls in the central region of Tn*3* and is called by Heffron the internal resolution site (IRS). The DNA sequence of IRS shows some similarity to the terminally repeated DNA sequences but the IRS sequence is unable to substitute for a terminal repeat in transposition. So here we have clear evidence that there is another sequence required in cis for transposition to occur. In addition to IRS there is a resolution function which may be supplied in trans. This function was shown by Sherratt (Glasgow University) to be coded by Tn*3*. Sherratt's studies shows the resolution function to map close to a gene whose product is known to repress transposition. Whether the resolution of co-integrates is another function of the previously defined repressor is not known. Resolution of co-integrates may be a site specific recombination catalysed at a high frequency by two copies of IRS and repressor.



(*a*) *Structure of transposon Tn*3, (*b*) *the transposable element is inserted into another replicon via a cointegrate.*

Genetic studies of Tn*3* have shown that the rate of transposition is influenced by genes carried by Tn*3*. Biek (Utah University) has used transposon Tn*5* to investigate another feature of regulation. In transductional crosses a Tn*5* element in the recipient cell inhibits transposition of the incoming Tn*5*. These results are consistent with a Tn*5* coded repressor of transposition. Genetic mapping localised the inhibition close to the Tn*5* drug resistance marker, neomycin phosphotransferase. However, the two functions are distinct since nonsense mutants of the *neo* gene do not affect transposition. The DNA sequence of Tn*5* has been established (Auerswald, Heidelberg University) and the transcription and translation products identified (Reznikoff, University of Wisconsin), so we can soon expect to know the molecular basis of Tn*5* mediated immunity.

The terminal inverted repeats of Tn*5* are much larger than those of Tn*3* and Reznikoff's laboratory has shown that each arm codes for two polypeptides but the molecular weights of the two proteins coded by each arm differs. Genetic studies have also shown that the two arms are not homologous. Mutations in the repeat proximal to the *neo* gene do not affect transposition but mutation of the distal arm can prevent transposition. The reason for this is apparent now that the DNA sequence of Tn*5* is known. The two arms differ by only a single base in 1,450 base pairs but this generates a stop codon in the coding sequence of the repeat proximal to the *neo* gene so bringing about the altered proteins and the lack of function. Grindley (Yale University) generated variants of the similarly organised transposon Tn*903* which have deletions in one arm. He then mutated the other inverted repeat by inserting 10 base pair Bam HI linkers at suitable restriction sites. This method of *in vitro* mutagenesis, extensively used by Heffron, generates frame shift mutations as the insertion is not an integer multiple of the three base codon. Grindley found that most double mutants of Tn*903* had lost the ability to transpose. The one exception which still transposed had suffered only a 9 base insertion, presumably leaving the distal part of a gene in phase. Although this is good genetic evidence for the expression of a gene in the inverted repeats of Tn*903* no protein has yet been found. How this expression leads to transposition is still not clear.

In Tn*5*, Tn*903*, Tn*3* and in bacteriophage Mu genetic and structural studies have identified genes and in some cases gene products which must mediate and regulate transposition. No *in vitro* assay for transposition is available, nor has enzymatic activity been associated with any of the putative transposases.

How does transposition occur? There may not be a single answer to this question. For example IS*4*, unlike most transposable elements, is site specific. Quite rightly these exceptions do not prevent the search for a single unifying model. As it is generally accepted that a copy of a transposon remains at the original site when transposition occurs, and because replication is actively required for transposition, a phage lambda-like excision-integration system is not favoured. A number of different copy-replication models are available. Harshey and Bukhari (Cold Spring Harbor) have visualized the DNA structures found when the bacteriophage Mu is induced. Mu can only replicate by transposing so a large number of transposition events are found in a single cell. Harshey and Bukhari see DNA structures which can be explained by a 'roll-in' mechanism which can initiate at either end of Mu.

The gene conversion system which controls mating type in yeast may be similar to a transposable system but under careful cellular control. The cassette model for mating type expression holds that

0028-0836/80/380188-02$01.00

information from either of two silent loci is sequentially expressed after transposition to a third (MAT) active locus this transposition is similar to that in prokaryotes as the information remains unchanged at the donor site. The focus of both molecular and genetic studies reported by three groups, Nasmyth (University of Washington), Klar (Cold Spring Harbor) and Haber (Brandeis University), is the cellular control of these three loci. It is not clear how sequences transposed to the *MAT* site become active. The active *MAT* site is a complex locus each *MAT* allele coding for two genes, divergently transcribed from opposite strands (Nasmyth and Klar). Yeast strains carrying recessive mutations in unlinked regulatory genes can express the silent mating type cassettes which shows that the silent copies, normally under negative control in trans, are relieved from this control when the information is switched to the active mating type locus. This rules out a system of the type demonstrated for sarcoma viruses where the cellular *sarc* structural gene and a strong promoter can be brought together to transform cells with high efficiency. Lambda-like independent excision and integration events were ruled out by evidence presented by Klar. He favored a duplicative transposition mechanism where the silent locus physically interacts with MAT since recombinants between MAT and the silent loci have been observed. The genetic studies of Haber (Brandeis University) were also consistent with this view.

Another eukaryotic system where genes are expressed in a mutually exclusive fashion occurs in the protozoan responsible for sleeping sickness. This parasite escapes from the host immune response by altering the dominant surface antigen which constitutes 95% of surface protein. Individuals of the species *Trypansoma brucei* have the ability to express one of many hundreds of special genes as this surface protein and so escape the host immune response. It appears now from work reported by Borst (University of Amsterdam) that at least some genes are moved to special genomic sites to become active. This may be the first generalization of the yeast cassette model and it is intriguing to speculate that other classes of genetic differentiation may be achieved by moving information around the genome.

What are we to make of all this genetic instability? Work on the proteins which mediate genetic recombination: recA, recBC, synaptase and the topoisomerases, emphasizes the ease with which the DNA may be rearranged. At least two conclusions follow: first, where genetic maps are conserved between bacteriophages or between the human and mouse X chromosomes this arrangement must have a selective advantage. Second, there may be systems where widespread genetic rearrangement is favoured over the usual conservative gene arrangement. We known of some of these situations; the recovery of bobbed *Drosophila* and the amplification of *Xenopus* ribosomal genes. A report by Jones (Edinburgh University) suggests that we may no longer be able to relegate these rearrangements to the miscellaneous file. He has found a sequence in the heterogametic W chromosome of female snakes which is conserved in echinoderms, *Drosophila* and mammals. This repeated sequence has at least two dramatic properties. Its sequence arrangement in different tissues of *Drosophila* varies and in mammals, its arrangement in males and females differs. When sex reversed Sxr mice which are phenotypically male but have a female karyotype were tested they exhibited the male pattern. If it is true that Sxr males are not Y autosome translocations but express constitutively the gene normally triggered by a Y chromosome signal, the implication is that the genomic rearrangement is a secondary sexual characteristic. This hypothesis could be tested by examination of another mouse strain Tfm (testicular feminisation) and of bovine freemartins where hormonal regime rather than genetic inheritance is known to mediate altered sexual differentiation. It is a measure of how far our views have changed that Jones' findings were met with interest and not instant disbelief. Of course we are now confident that the clones and blots will tell all. □

100 years ago

The *Philadelphia Record* deserves credit for its successful efforts to break up the sale of bogus medical diplomas. These diplomas were chiefly sold abroad, and it is appalling to learn, that 11,000 of them have been issued during the past few years. "It was well known," the *Times* correspondent writes, "that Dr. John Buchanan, the Dean of 'The American University of Philadelphia,' and several other similar institutions, was engaged in this traffic; but as they were all properly chartered medical schools, and, though disreputable, existing under the sanction of law, the difficulty was to get evidence of the sale of diplomas. Diplomatic complaints about the traffic came from various Governments of Europe, and our people began to be restive under the stigma." By the clever tact of the city editor of the *Record*, however, Buchanan has been brought within reach of the law, and the detectives are on his track. He attempted to put them off the scent by getting a man looking like himself to pretend to drown himself; this bogus case of drowning, however, has deceived nobody.

The nature of gravitation

from A.H. Cook

EXPERIMENTAL studies of gravitation have been discouraged by the attitude of many theoreticians who, from the time of Newton, have taken gravitation as something 'given'. Experimenters are not, however, so easily put off by theoretical detachment even though the very small strength of gravitation makes its investigation difficult — the gravitational force between proton and proton is about 10^{-39} of the electrical force which, in practice, means that any laboratory study of gravitation will be bedevilled by all manner of extraneous disturbances.

A simple-minded approach to the experimental study of gravitation is to look at the inverse square law and ask such questions as: what is the 'mass'? Is it always proportional to inertial mass or are there differences from substance to substance? Is there any screening of one body by another, as with electrostatic forces? Is the 'constant' of gravitation constant, or does it depend on velocity, time, position, or the direction of the line joining two attracting bodies, and finally, is the inverse square law strictly obeyed?

We have experimental answers to these questions for the electrostatic force, and they are expressed in the appropriate Maxwell equations. We have some answers for gravitation. Experiments for many years have failed to detect any dependence of gravitation upon material — all hadrons are equivalent gravitationally to within about 1 part in 10^{11}. A few astronomical and geophysical observations have shown the absence of any shielding effect to about the same limit. Geophysical observations of Earth tides show that if there is any dependence of gravitation on direction it cannot exceed 1 part in 10^{8}. These and other effects can be incorporated in certain sorts of theory known as parameterised post-Newton (PPN) gravitation theories, provided sufficient parameters are included. If some of these parameters differ from the values predicted from general relativity, then certain effects in celestial mechanics would occur and might be detectable in refined observations of space craft or the Moon. Although such observations, for example, laser ranging measurements of the orbital motion of the Moon, are now possible, no derivations from the predictions of general relativity have so far been detected.

It should be emphasized that the type of experiment being considered is quite different from attempts to detect gravitational radiation. No one seriously doubts that radiation is entailed by general relativity but the question is whether any object radiates strongly enough to be observed with techniques available on Earth.

With the growth of interest in unified theories of gravitation and other inter-

0028-0836/80/380189-02$01.00

actions, it is natural to suppose that there should be a particle having a finite mass which arises from some broken symmetry in the field theoretic description of gravitation, and it has been suggested that the gravitational potential energy of two masses would not be simply proportional to $1/r$, where r is their separation, but would be given by

$$\frac{G_o M_m (1 + \alpha \exp(-r/\lambda))}{r}.$$

This gives an inverse square law dependence at small distances ($r << \lambda$) and at large distances ($r >> \lambda$) and the ratio of the respective "constants" of gravitation is $(1 + \alpha)$.

Could this , or some other departure from the inverse square law be detected? Long (*Nature* **260**, 417; 1976) claimed to have found such an effect but in a recently published experiment by Spero *et al.* (*Phys. Rev. Lett.* **44**, 1645, 1980) no deviation was detected. As is well known, very delicate tests of the inverse square law of electrostatics can be made using the principle that the field inside a charged sphere vanishes. Construction of a hollow sphere for a gravitational experiment is hardly possible so Spero and his colleagues investigated the gravitational field inside a long tube. Were the tube infinitely long there would be no net internal field but with a finite cylinder there are end effects. The experiment was designed to use a sensitive torsion balance to measure the change in force on a test mass in different radial positions within a long vertical cylinder. A servo-control was applied to the torsion balance to maintain it in a constant position and the restoring force necessary to do so was recorded for different positions of the cylinder relative to a test mass suspended from one end of the balance beam. To attain a useful precision, the experiment had to be very carefully designed. Corrections were determined for the end effects and other stray gravitational fields and precautions were taken against magnetic and convective forces. The experiment depended on the material of the cylinder (which was of stainless steel, 60 cm long, of 6 cm internal diameter and a mass of about 10 kg) being very uniform, and a careful study of the cylinder had therefore to be undertaken. The measured torques were of the order of 5.10^{-13} Nm, showing the extreme delicacy that must be attained in worthwhile experiments on gravitation. The observations agreed with the torque predicted for pure inverse square law attractions to 2.10^{-15} Nm, a result that is inconsistent with Long's earlier study.

It can be said that no deviation of the behaviour of gravitation from the predictions of general relativity has as yet been established experimentally, and one may suspect that none will be. That, however, is not a reason for abandoning experiments such as those mentioned earlier. Gravitation is such a fundamental interaction that it is a worthwhile aim to establish its properties to the very highest precision, particularly since to do so presents a daunting but irresistible challenge to the experimenter. □

Terrestrial heat flux

from David S. Chapman

PRESENT day heat loss through the Earth's crust is approximately 4×10^{13} Joules and as such is of major importance in geodynamic processes. The source of the heat, its mode of transport and its geographical pattern of variation are still questions which remain largely unanswered and they provided the central theme for a recent conference*.

Heat flow measurements have still not been made from many parts of the world so one of the highlights of the conference was the addition of data from China to the global heat flow map. Ji-Yang Wang (Academia Sinica, Beijing) reported that twenty-two values from north China fall into the following patterns: heat flow of 32mW m^{-2} in the Archean crust of central Yanshan; 54 to 75 mW m^{-2} in the neotectonic Huailai and Yanquing basins, and 61 to 84 mW m^{-2} on the block faulted North China Plain (see *J. Volcanol. Geotherm. Res.* in the press) where tectonic activity, according to Wang, "has been strengthening since the Mesozoic era". The Chinese territory also received attention from Anderson (Lamont-Doherty Geological Institute, Columbia) in his report of the first detailed heat flow profile across a continental margin. The demonstration of stable bottom water temperatures on the margin, a prerequisite for shallow marine measurements, will encourage further experiments in spite of the monotony of the results — a uniform 90 mW m^{-2} with one unexplained anomaly in 88 measurements.

In another pioneering effort, Bucher and Decker (University of Wyoming) reported values between 50 and 84 mW m^{-2} in the Ross Island dry valley area of Antarctica. These results significantly extend the coverage of heat flow measurements on the globe. None of the new results depart from the heat flow patterns established elsewhere in the world — heat flow is elevated in young orogenic provinces and decays systematically with increasing geological age — but do allow a better contouring of the global data set.

One issue beginnning to be resolved by the increasing number of heat flow observations is the nature and width of heat flow transitions. That heat flow transitions of 30 mW m^{-2} and greater commonly occur over lateral distances of 10 to 50 km was demonstrated in an analysis of existing data for rift valleys (Morgan, New Mexico State University), by new data from the Southern Rocky Mountains (Decker, University of Wyoming), and by independent new surveys by Stone (University of Arizona) and Chapman and colleagues (University of Utah) of the transition from the Basin and Range to the Colorado plateau physiographic province. In areas where few measurements existed, the transition had been considered to be broad and the source thermal perturbation confined to the asthenosphere. The observations of sharp transitions imply that heat sources must be shallow, within the lithosphere or possibly even within the crust. As the calculation of geotherms, regularly used to predict rheology, mineralogy and partial melting in the lower lithosphere, is critically dependent on the depth distribution of heat sources, modification of much used purely conductive geotherms in certain regions now seems appropriate (as suggested by Lachenbruch & Sass *Geol. Soc. Amer. Memoir* **152**, 209; 1978).

A further caution to those who seek deeper meaning from all heat flow anomalies came from three studies of the role of groundwater in redistributing heat. Heat flow investigators for several years have inferred the role of groundwater in transferring heat, especially in very young oceanic crust, but the direct demonstration of those flows has been difficult. Therefore, the experiments described by D. Abbot and colleagues (Lamont-Doherty) on the simultaneous measurement of excess pore pressure and temperature gradients in sediments covering 22 Myr old crust in the Guatemala Basin is of special significance. The objective was to explain very low observed heat flows of 1 to 20 mW m^{-2} in the region instead of the 105 mW m^{-2} expected on the basis of crustal age. Although measured temperature-depth profiles were linear, usually an indication that convective disturbances are absent, all of the new measurements yielded negative pore pressures within the sediment, indicating downward fluid velocities between 10^{-6} and 10^{-7} cm s^{-1}. Such velocities are sufficient to decrease heat flow by a factor of 10. More important, they confirm the long held suspicion that many subnormal oceanic heat flow areas actually delineate the downgoing side of a sea floor convec-

tion system.

On a larger scale of tens of kilometers, groundwater flow was also shown to have major effects on observed heat flow patterns. Lohse, Morgan and Swanberg (New Mexico State University) reported 60 new heat flow determinations from the Rio Grande Rift zone and interpreted the highly variable pattern in terms of ascending warm water in rift fracture zones and intrabasin groundwater flow in the Rio Grande River drainage system. In perhaps the best example of redistribution of crustal heat over lateral distances of hundreds of kilometers, Majorowicz (Warsaw University) demonstrated that a relatively low heat flow of 50-75 mW m^{-2} in the Rocky Mountain foothills of Alberta and an abnormal heat flow of 70-100 mW m^{-2} in the northern Prairies Basin could only be explained by regional groundwater flow.

In contrast to the previous discussions on patterns and mode of transport of the terrestrial heat flux, two papers addressed the source of heat, at least the crustal radiogenic portion now thought to account for about 40% of the continental flux. Our present understanding of this radiogenic heat distribution hinges on the empirical relationship between surface heat flow and surface radioactive heat production first demonstrated in 1968 for plutons by Birch and co-workers, and modeled soon afterwards by Lachenbruch. According to these early models, plutons undergo an upward enrichment in uranium, thorium and potassium, the important heat producing elements. Their combined depth distribution is characterized by the length parameter *b*, the slope of heat flow-heat production line for that pluton. Any of three depth distributions, constant to depth *b*, linearly decreasing to depth 2 *b*, or expotentially decreasing with characteristic decrement *b*, satisfy the heat flow–heat production relationship, although the latter makes the most geological sense.

Now Gosnold (Nebraska University) and Jaupart (University of Paris) have independently suggested modifications to this model and its interpretation. Gosnold has combined fission track, petrographic and oxygen isotope studies on samples from several plutons within the Idaho Batholith. His results suggest, not surprisingly, that heat generation is largely controlled by water–rock interaction in the upper 10 km of the crust. In such a case the overall vertical heat production distribution could be exponential throughout the crust but an inflection in the curve would occur at the lowest depth of meteoric water interaction. Jaupart's modification is more severe. He questioned the assumption that uranium, thorium and potassium have identical depth distributions. He has inferred from his preliminary analysis, although based on surface sampling only, that the three elements have different depth distributions but are similar from one geological province to another. Both these suggestions have interesting geochemical and geophysical implications and it is a pity therefore that the issues may not easily be resolved. The characteristic scale for these processes and the radioactive enrichment is 10 km, and few, if any, geological locations permit sampling over that vertical extent in the igneous crust. ☐

Myosin phosphorylation

from Dixie W. Frederiksen

REGULATION of muscle contraction and cell motility occurs by the control of the interaction of actin and myosin. Primary control is exercised by the intracellular calcium concentration and is modulated at secondary levels by various mechanisms that seem to depend upon the source of the tissue or proteins examined. Myosin phosphorylation plays an important role both in the primary regulation and in the secondary modulation of contraction and motility[1].

In vertebrate striated muscle the binding of calcium to troponin, a protein on the actin filament of the muscle sarcomere, is clearly the event that triggers actin-activation of the MgATPase. Although the direct steric blocking model for this actin-linked regulatory mechanism[2] has been challenged recently[3] there is little debate that troponin and tropomyosin are responsible for primary regulation in vertebrate striated muscles. At the secondary level, phosphorylation of a troponin subunit by cyclic AMP-dependent protein kinase has been shown to result in decreased actin-activated MgATPase activity of striated muscle myosin[4]. Furthermore, although striated muscle myosin phosphorylation was discovered sometime ago by S. V. Perry and his colleagues at the University of Birmingham[5], the function of this modification is still largely unknown. The phosphorylation is presumed to play a secondary role in modulation of the contractile process.

In many smooth muscle and nonmuscle actomyosin systems it seems clear that the calcium-sensitive mechanism responsible for primary regulation is myosin-linked through phosphorylation of one of the small subunits of the myosin molecule. David J. Hartshorne and his collaborators[6] at the University of Arizona and Robert S. Adelstein with his colleagues at the N I H[7] have shown in several elegant experiments that the binding of a calcium-calmodulin complex to myosin light chain kinase and the subsequent phosphorylation of myosin are the initial steps in actin-activation of smooth muscle and some of the nonmuscle myosin MgATPases. The secondary modulation of contraction/motility in these systems seems to include one or more different processes. Cyclic AMP-dependent protein kinase-catalysed phosphorylation of myosin light chain kinase was discovered by the Adelstein group[8] and found to result in decreased activity of the myosin light chain kinase. In addition, direct interaction of calcium with phosphorylated smooth muscle myosin has been reported to modulate the actin-activated MgATPase[9].

The effects of myosin phosphorylation on the contractile apparatus are complex and subtle and reports of the influence of myosin phosphorylation on striated muscle proteins *in vitro* have not been forthcoming. As a result, investigators have turned to the examination of intact muscle for evidence of the effects of phosphorylation. Michael Bárány and his colleagues at the University of Illinois Medical Center[10] have used frog muscle and James T. Stull and his group at the University of Texas Health Science Center[11] have used mammalian striated muscle to monitor the phosphorylation. In these *in situ* studies, phosphorylation of myosin light chain was observed to be correlated with the stimulation of the muscle. Bárány has suggested that the function of the phosphorylation may be to increase the actin-myosin affinity by the formation of a salt-bridge between the phosphoryl group on myosin and the actin-bound calcium on the thin filament. Such an increased affinity would lead to an increased rate of combination of myosin crossbridges with the actin filament.

The phosphorylated myosins of smooth muscle and several nonmuscle systems, unlike their striated muscle counterparts,

Bishop Wilberforce: Natural Selection and the Descent of Man

from Richard W. Wrangham

Samuel Wilberforce, Bishop of Oxford, was the man who played into T.H. Huxley's hands at the British Association's meeting in 1860. They were debating the merits of Darwinism, and the atmosphere in the crowded room was highly charged. Wilberforce was a fine speaker — "Like an olive, his nature secretes his own oil", wrote *Punch*[1] — and he ended his well-prepared attack on evolutionary theory by asking if his opponent were prepared to admit apes to his own ancestry. The reply was deadly. An ape, said Huxley, would be a preferable grandfather to an intelligent man who used his skills to bring ridicule to science.[2] It won the audience and silenced the Bishop, who never spoke again on evolution.

Huxley went on to build a career out of promoting Darwinism, while Wilberforce returned to ecclesiastical matters. But how did he come to feel about evolution? His only published opinion was a review of the *Origin of Species*, written before the debate with Huxley.[3] There he denied unambiguously that evolution was tenable, though he approved of natural selection. He understood the arguments well and used them to maintain that selection acted to keep species constant, not to change them[4].

Now a clue to his subsequent feelings has emerged. The poem below was found earlier this year in his private papers, and is undated. Its theme, "degradation by natural selection", is from Richard Owen's review of the *Origin.*[5] Wilberforce saw all too well the clash between evolutionary theory and his religious beliefs, and in 1860 he had come out in attack. But in this poem he side-stepped the conflict and retreated to comedy. It implies a man too committed to accept the evolutionary argument, yet too honest in the end to deny it. Who knows? Darwin may have had one more convert than he knew.

"Lines written on hearing that Professor Huxley had said that 'he did not care
whether his grand-father was an Ape'."

Oft had I heard, but deemed the tale untrue,
That man was cousin to the Kangaroo;
That he before whose face all nature quailed,
Was but the monkey's heir, though unentailed;
And that the limber Ape, whose knavish ways
And tricks fantastic oft our laughter raise,
Was just what *we* were in some previous state,
Ages ere Noah shipped his living freight.
But now a learn'd Professor, grave and wise,
Stoutly maintains what I supposed were lies;
And, while each listening sage in wonder gapes,
Claims a proud lineage of ancestral Apes.
Alas! cried I, if such the sage's dreams,
Save me, ye powers, from these unhallowed themes;
From self-degrading science keep me free,
And from the pride that apes humility!
But O should fate bring back these dreams accursed,
And shuddering Nature find her laws reversed;
Should this, the age of wonders, see again
Men sunk to monkeys, monkeys raised to men:
Be mine the lot, on some far-distant shore,
Where Science wearies not nor savants bore —
Where no learn'd Apes our fallen race may scorn,
Nor point the moral which our tails adorn —
To shun the sight of metamorphosed friends,
Till time again shall shape their altered ends,
To soothe each fond regret, howe'er I can;
And, at the least, to dream myself a Man!
S. Wilberforce

have properties that are readily observed *in vitro* and are clearly distinct from those of the unphosphorylated protein. The influence of phosphorylation on the potentiation of the actin-activated myosin MgATPase has been the major focus of attention. Upon phosphorylation of the myosin light chain, the MgATPase activity of the protein in the presence of actin is increased ten- to twentyfold[12].

A third manifestation of the effect of myosin phosphorylation has now been observed *in vitro* with myosin from smooth muscle and nonmuscle cells. Working with myosins from thymus, platelets and gizzard, John Kendrick-Jones *et al.* show in this issue of *Nature* (p.233) that bipolar thick filaments are formed under physiological conditions only if the myosins are phosphorylated. These synthetic thick filaments are stable in the presence of millimolar concentrations of MgATP. Shorter filaments are formed of unphosphorylated myosins *in vitro* at low ionic strength, but these are completely dissociated well below physiological concentrations of MgATP. These results are a striking extension and confirmation of the work by Hiroshi Suzuki and his collaborators at the Tokyo Institute of Technology[13] who first observed that the state of gizzard myosin phosphorylation has a profound effect upon the ability of the protein to form extended aggregates.

The observations of Suzuki and of Kendrick-Jones are particularly important because they resolve some puzzles and raise some interesting questions. If smooth muscle and non-muscle myosin must be phosphorylated in order to form thick filaments *in vivo,* then the absence of such filaments in many electron micrographs of smooth muscle and nonmuscle cells might be explained by the absence of phosphorylated myosin. Furthermore, another possible function of phosphorylation in striated muscle becomes clear — phosphorylated, striated muscle myosin may constitute thick filaments more stable and/or more ordered than the unphosphorylated myoisin.

The questions are intriguing. How does filament formation contribute to the observed actin-activation of the smooth muscle and nonmuscle MgATPase? Is actin-activation due to an increased order in the myosin array and, therefore, to an increased accessibility of myosin to actin? Another very important question raised by Kendrick-Jones has to do with how modification of the head portion of myosin might influence the association and packing of the opposite, tail portion of the molecule. No doubt subsequent studies by these and other investigators will address these problems and will shed even more light upon the nature of the finely tuned control in the contractile protein complex. □

Expression of human fibroblast interferon gene in *Escherichia coli*

Rik Derynck*, Erik Remaut*, Erik Saman*, Patrick Stanssens*, Erik De Clercq†, Jean Content§ & Walter Fiers*

* Laboratory of Molecular Biology, State University of Ghent, Ledeganckstraat 35, B-9000 Ghent, Belgium
† Rega Institute for Medical Research, Katholieke Universiteit Leuven, Minderbroedersstraat 10, B-3000 Leuven, Belgium
§ Institut Pasteur du Brabant, rue du Remorqueur 28, B-1040 Brussels, Belgium

The human fibroblast interferon gene was inserted in a thermoinducible expression plasmid under control of the phage lambda P_L promotor. The primary translation products predicted on the basis of the plasmid constructions were hybrid proteins starting with β-lactamase or phage MS2 polymerase information followed by the total preinterferon. On induction, antiviral activity, whose physico-chemical, immunological and biological characteristics closely corresponded to those of authentic human fibroblast interferon, was synthesized. Processing to a size compatible with mature but unglycosylated authentic product was observed.

ON exposure to viruses or other specific inducers most vertibrate cells secrete protein(s) with broad antiviral action known as interferons. Human interferons are being intensively studied for their antiviral[1], anticellular[2] and immunomodulating[3] activities. Clinical trials have been carried out mainly with leukocyte interferon but also with fibroblast interferon, and some promising results have been obtained with both types in the treatment of viral diseases and cancer[1,4–9]. Tests with fibroblast interferon have been severely restricted by its very limited availability.

In a previous report[10], we described the construction and characterization of chimaeric plasmids containing human fibroblast interferon (HF–IF) cDNA. Two other groups have constructed plasmids containing either human leukocyte[11] or human fibroblast[12] interferon cDNA and in the former case, interferon-related polypeptides, as judged by biological and immunological criteria, were detected in *E. coli* strains harbouring the chimaeric plasmids. We have now inserted the HF–IF coding sequence derived from our original clones into appropriate sites on specifically constructed expression vehicles which contain the strong leftward promoter (P_L) of bacteriophage λ. The functioning of the promoter could be controlled by using host strains which synthesize a temperature-sensitive repressor (cI-ts). We describe here how plasmids containing P_L in front of the HF–IF coding sequence direct the synthesis of polypeptides with human fibroblast interferon activity in *E. coli*.

Construction of plasmids allowing expression of HF–IF

Construction of the different plasmids containing HF–IF DNA under the control of lambda P_L is schematically represented in Fig. 1. The formation and use of acceptor plasmids pPLa2311, pPLa8 and pPLc24 will be published in detail elsewhere (E. Remaut *et al.*, in preparation).

None of the chimaeric plasmids previously described contains an uninterrupted HF-IF gene[10]. A complete and continuous coding sequence for HF–IF was reconstituted by inserting an *Eco*RI-*Pst*I fragment from pHFIF-6 and a *Pst*I-*Hae*II fragment from pHFIF-7 into the plasmid pPLa2311. From the resulting plasmid, designated pPLa-HFIF-67-1, a *Bgl*II fragment was excised and ligated into the *Bam*HI site of the β-lactamase region of pPLa8 in the sense orientation with respect to the P_L promoter. The known nucleotide sequence around the *Bam*HI-*Bgl*II junction in this plasmid, pPLa-HFIF-67-12, predicts that a polypeptide initiated at the AUG of the β-lactamase part will terminate on a double amber stop codon in the 5′-untranslated region of the HF–IF gene, 23 nucleotides before the HF–IF initiating AUG (data not shown).

pPLa-HFIF-67-12Δ19 was derived from pPLa-HFIF-67-12 by deleting a *Hin*dII fragment starting within the β-lactamase gene and extending up to three nucleotides before the HF–IF initiating AUG (Fig. 1). From the known nucleotide sequence of the β-lactamase gene (as determined on the progenitor pBR322)[13] and of the HF–IF gene[10], a continuous reading frame starting at the initiating AUG of the β-lactamase gene and running up to the terminating UGA of the HF–IF gene is predicted. The expected fusion polypeptide consists of 82 amino acid residues of the β-lactamase protein, one amino acid coded for at the fused *Hin*dII site, and the complete polypeptide (including the putative signal sequence) specified by the HF–IF gene. The predicted sequence around the junction is: β-lactamase gene moiety-GUU.AAC. AUG-HFIF gene, where the GUU triplet codes for amino acid 82 of the β-lactamase protein.

Alternatively, a hybrid plasmid with the controllable lambda P_L promoter in the clockwise orientation was constructed. The acceptor plasmid was pPLc24, which contains the P_L promoter followed by an *Eco*RI-*Bam*HI fragment (derived from pMS2-7 [ref. 14]) containing the ribosome binding site and part of the MS2 polymerase gene. The pPLa-HFIF-67-1 *Bgl*II fragment containing the HF–IF gene was inserted into the *Bam*HI site of pPLc24, resulting in loss of *Bam*HI and *Bgl*II sensitivity but formation of *Sau*3AI sites at the joints (Fig. 1). In this new plasmid, pPLc-HFIF-67-8, a continuous reading frame starting at the initiating AUG of the MS2 polymerase gene and terminating at the UGA of the HF-IF gene, can be predicted on the basis of the known nucleotide sequences of the MS2 polymerase gene[15] and of pHFIF-6 and pHFIF-7 (ref. 10). The expected fusion protein consists of the N-terminal 98 amino acids of the MS2 polymerase moiety, 27 amino acids coded for by sequences between the *Bgl*II site and the initiating AUG of the HF-IF gene, followed by the complete HF–IF coding region,

0028-0836/80/380193—05$01.00

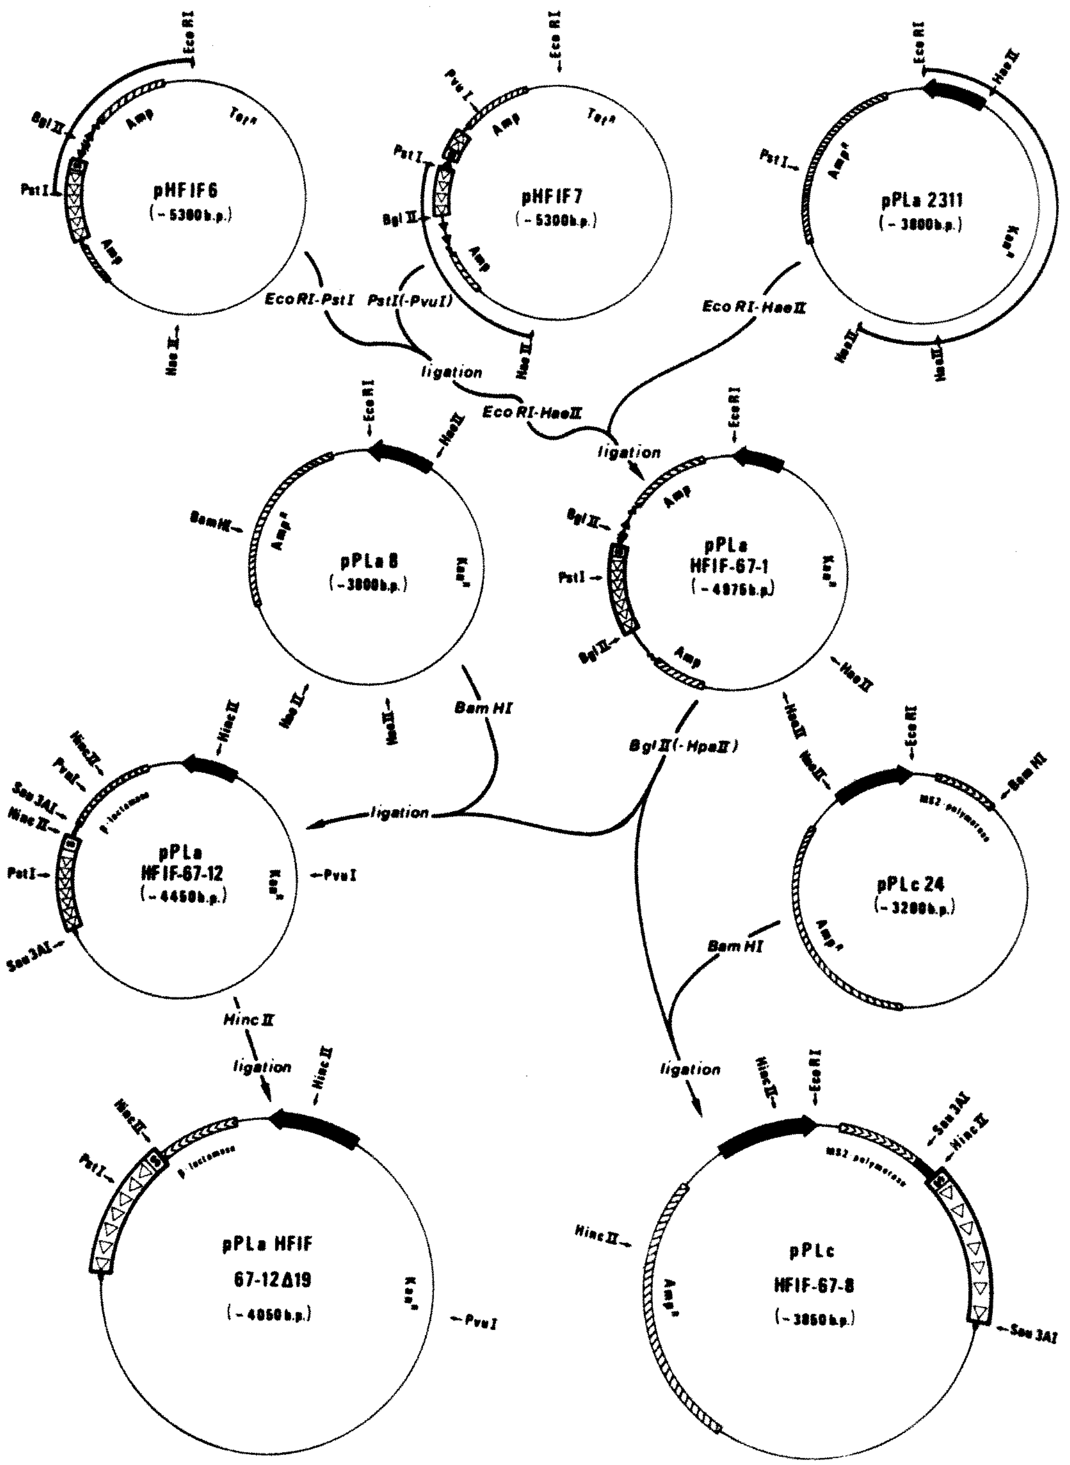

Fig. 1 Schematic outline of the construction of the different plasmids. The HF–IF DNA is indicated by a heavy line, the boxed area being the coding region with the putative signal peptide (S); the triangles indicate the 5'→3' direction of the insert. The heavy arrow indicates the lambda P_L-promoter control element. The ampicillin-resistance region is shown as a shaded area. An interruption of the base line in the insert shows the cross-over region of the inversions of our original HF–IF cDNA-containing plasmids[10]. dA·dT tails are indicated by a wavy line. Amp, β-lactamase region coding for resistance to ampicillin and carbenicillin; Kan, region coding for kanamycin resistance. To construct pPLa-HFIF-67-1, pHFIF-6 DNA was cleaved with *Eco*RI and *Pst*I and ligated to pHFIF-7 which had been cleaved with *Pst*I and *Pvu*I. Following ligation, the mixture was digested with *Eco*RI and *Hae*II and ligated to pPLa2311 which had been digested with *Eco*RI and partially with *Hae*II. The segments of the outer circles indicate the fragments retained in the pPLa-HFIF-67-1 construction: only those restriction sites relevant to the constructions are indicated. Transformants were obtained in $C600r_K^-m_K^+(\lambda)$ with selection for kanamycin resistance and screened for sensitivity to carbenicillin. The structure of a representative plasmid, pPLa-HFIF-67-1, was confirmed by digestions with *Eco*RI, *Pst*I, *Bgl*II and *Hin*cII (=*Hin*dII). To construct pPLa-HFIF-67-12, the HF–IF gene was excised from pPLa-HFIF-67-1 with *Bgl*II, followed by fragmentation of the remaining part of the plasmid with *Hpa*II, which does not cut the HF–IF gene. The DNA was ligated to pPLa8, which had been opened with *Bam*HI. After ligation, the mixture was redigested with *Bam*HI to eliminate recircularized pPLa8 acceptor plasmids. Transformants were obtained in $C600r_K^-m_K^+(\lambda)$ by selection for kanamycin resistance. The structure of pPLa-HFIF-67-12 was examined by analysis with *Pst*I and *Hin*cII. To construct pPLa-HFIF-67-12Δ19, pPLa-HFIF-67-12 was partially digested with *Hin*cII and ligated at a low DNA concentration (0.01 μg ml^{-1}). The mixture was then digested with *Xor*II, an isoschizomer of *Pvu*I producing 3'-protruding ends[26], and religated at low DNA concentration, thereby substantially reducing the probability of religation of the original pPLa-HFIF-67-12 plasmids. The structure of pPLa-HFIF-67-12Δ19 was examined by digestion with *Hin*cII and *Pvu*I. To construct pPLc-HFIF-67-8, the DNA of pPLa-HFIF-67-1 was digested with *Bgl*II and ligated into the *Bam*HI-opened pPLc-24 DNA. The ligation mixture was redigested with *Bam*HI to eliminate religated parental pPLc-24 plasmids. Transformants were selected for resistance to carbenicillin. The insertion and orientation of the *Bgl*II HF–IF fragment was established by *Hin*cII digestion. Restriction enzymes (Biolabs, Boehringer or BRL) were used according to the manufacturer's specifications. Ligations were carried out at 22 °C with T4 DNA ligase in Tris-Cl (50 mM, *p*H 7.6), $MgCl_2$ (5 mM), β-mercaptoethanol (7 mM), ATP (50 μM), (ref. 27). All plasmids were subsequently transferred into *E. coli* M5219 (K12 M72 lac_{am} trp_{am} Sm^R [λCI857ΔHI bio 2521])[16]. Enzymatic reactions were stopped by heating at 65 °C for 10 min.

including the signal peptide. The predicted sequence around the junction is

The first amino acid, tryptophan, corresponds to position 98 of the MS2 polymerase.

All constructed chimaeric plasmids were transformed into *E. coli* C600$r_K^-m_K^+$(λ) and, after characterization, transferred into *E. coli* M5219 (ref. 16), allowing the temperature-dependent controlled expression of the lambda P_L (E. Remaut *et al.*, in preparation).

Detection of IF activity in bacterial extracts

Transcription from the P_L promoter on the plasmids can be turned on by shifting the growing culture from 28 to 42 °C. The synthesis of IF-related product(s) was examined by assaying an S100 extract of the bacteria for antiviral activity (Table 1). The cells were lysed either by lysozyme treatment followed by freeze-thawing or by heating in 1% SDS, 1% β-mercaptoethanol, 5 M urea. The extracts of temperature-induced *E. coli* M5219 containing pPLa-HFIF-67-12Δ19 or pPLc-HFIF-67-8 showed a clear antiviral activity, which was reproducibly higher with the latter plasmid. The same non-induced strains as well as induced M5219 containing a reference plasmid (pPLa8) did not show any detectable activity. In M5219 containing pPLa-HFIF-67-12, trace amounts of antiviral activity were occasionally detected after temperature shift (data not shown), presumably due to a rare reinitiation event. The much higher activity obtained after lysis with the SDS, β-mercaptoethanol, urea mixture indicates a possible nonspecific sticking of the antiviral product(s) to bacterial components, for example, cell membranes or nucleic acids. In parallel experiments in which authentic HF–IF was added to a control bacterial extract obtained by lysozyme treatment, only 10–40% of the activity was recovered.

Low but significant amounts of antiviral activity were detected in the supernatant after osmotic shock of induced M5219 transformed with pPLc-HFIF-67-8 (Table 1). When a more severe method of periplasmic extraction was used (that is, spheroplast formation), some activity was also detected with induced M5219 transformed by pPLa-HFIF-67-12Δ19. These results suggest that at least some of the bacterial HF–IF may be secreted into the periplasmic compartment, perhaps concomitantly with the removal of the signal peptide; other explanations, however, cannot be excluded.

Characterization of the bacterial IF activity

The antiviral activity detected in the above-mentioned extracts of induced bacteria was tested for several biological and physical properties characteristic of HF–IF (Table 2). First, the antiviral activity was non-dialysable; after dialysis for 16 h at neutral *p*H the antiviral activity was retained, albeit often at reduced levels (which was also the case for authentic HF–IF preparations). The observed decrease is presumably due to nonspecific sticking to the dialysis membranes, as HF–IF is known to be rather hydrophobic[17], and the unglycosylated bacterial form may be even more so. The antiviral activity could be recovered after precipitation with 67% saturated ammonium sulphate, a concentration known to precipitate HF–IF[18].

When tested for stability at *p*H 2, a common property of fibroblast and leukocyte interferon[1], bacterial HF–IF proved to remain active (Table 2), although again there was often partial loss of activity, but this was also the case with reconstituted authentic HF–IF controls.

The sensitivity of the bacterial HF–IF activity to protease was tested by treating the diluted bacterial extracts with increasing amounts of trypsin. The activity was abolished at the same concentration of trypsin that abolished the activity of authentic HF–IF added to an inactive control lysate.

HF–IF, in contrast to leukocyte interferon, is stable after heating in 1% SDS, 1% β-mercaptoethanol, 5 M urea[19], although we only obtained 10–20% recovery of activity with authentic HF–IF, either alone or in the presence of an inactive bacterial extract (data not shown). The bacterial HF–IF activity remained active in these conditions, as lysis of induced bacteria in this solution resulted in extracts with the highest antiviral titre (Table 1).

The antigenic properties of the *E. coli* IF activity were compared with those of authentic HF–IF. Serial dilutions of goat anti-HF–IF antiserum were incubated with diluted extracts containing bacterial HF–IF activity and with control HF–IF preparations in the presence or absence of an inactive bacterial lysate. The bacterial IF activity was neutralized by the specific antiserum, but some differences were noted in the neutralizing antibody titres for bacterial IF and authentic HF–IF (Table 2). Small differences in neutralization titre were also reported for bacterial leukocyte IF when compared with authentic leukocyte IF[11]. This can be explained by a difference either in antigenicity or in specific IF activity of these bacterial proteins relative to authentic IF.

Table 1 Interferon activity in extracts of *E. coli* M5219 transformed by expression plasmids containing the HF–IF coding sequence

		Interferon activity (units per ml extract) in			
Plasmid	Temperature	S100 extracts after lysis by lysozyme and freeze–thawing (I)	S100 extracts after lysis with SDS, β-mercaptoethanol, urea (II)	Periplasmic fraction: osmotic shock (III)	Periplasmic fraction: spheroplast formation (IV)
pPLa-HFIF-67-12Δ19	28 °C	<3; <2	<30; <100	<2	2
	42 °C	200; 20	200; 2000	<2	10
pPLc-HFIF-67-8	28 °C	<3; <2	<100; <100	<2	<2
	42 °C	200; 50	2,000; 3,000	30	30
pPLa8	42 °C	<3; <2	<100; <100	<2	<2

LB medium (150 ml) was inoculated with 1/500 volume of a fresh seed culture, saturated at 28 °C, and maintained with vigorous shaking at 28 °C until a cell concentration of 2×10^8 ml^{-1} was reached. Induction was by shifting the temperature to 42 °C and incubation of the cultures for 3 h to a final concentration of $4\text{–}6 \times 10^8$ cells ml^{-1}. The cells were collected and washed with Tris-HCl (50 mM, *p*H 7.4), NaCl (30 mM) and repelletted. Several different extraction procedures were used: I, the bacterial pellet was resuspended in a final volume (4 ml) with HEPES-NaOH (50 mM, *p*H 7.0), NaCl (30 mM) 3% calf serum, β-mercaptoethanol (3 mM), to which lysozyme (Sigma) was added to 1 mg ml^{-1}. After incubation at 0 °C for 30 min, the suspension was subjected to one or two freeze–thawing cycles. The S100 fraction was prepared by ultracentrifugation at 60,000 r.p.m. for 1 h in a Beckman SW60 Ti rotor. II, The cells were resuspended as in I and lysed in HEPES-NaOH (50 mM, *p*H 7.0), NaCl (30 mM), 3% calf serum, 1% SDS, 1% β-mercaptoethanol, urea (5 M) at 90 °C for 1–2 min. Clearing by ultracentrifugation was as in I. III, Osmotic shock procedure[21]: the bacterial cell pellet was resuspended in 20% sucrose, EDTA (100 mM), Tris-HCl (100 mM, *p*H 7.4), to a cell concentration of 1×10^{10} ml^{-1}. After 10 min at 0 °C, the suspension was centrifuged for 10 min at 10,000 r.p.m. The pellet was resuspended in water to a cell concentration of 1×10^{10} ml^{-1}. After 10 min on ice, the suspension was again cleared for 10 min at 10,000 r.p.m. To this osmotic shock supernatant was added HEPES-NaOH (50 mM, *p*H 7.0), NaCl (30 mM), β-mercaptoethanol (3 mM) and 3% calf serum. IV, Cells were resuspended in 3.6 ml of 0.1 M Tris-HCl, *p*H 8.0, 20% sucrose, to which 0.4 ml of lysozyme (5 mg ml^{-1} in EDTA [20 mM]) was added. After incubation for 30 min at 0 °C, the suspension was centrifuged for 10 min at 10,000 r.p.m. The supernatant was adjusted to 3% calf serum. IF activity was measured by a cytopathic effect (CPE)-inhibition assay on human fibroblasts trisomic for chromosome 21 in microtitre trays. The cells were challenged with vesicular stomatitis virus (Indiana strain) and the CPE was recorded at 24 h. All assays included an internal HF–IF reference which was calibrated against the NIH HF–IF reference G023-902-527. The limit of detection, normally 1 unit ml^{-1}, was often elevated due to toxicity of certain samples (for example, for the samples obtained with method II, the limit of detection was 30–100 units ml^{-1}). The titres are expressed in units ml^{-1}, although it should be noted that they were obtained by 0.5 $\log_{10}$ dilutions.

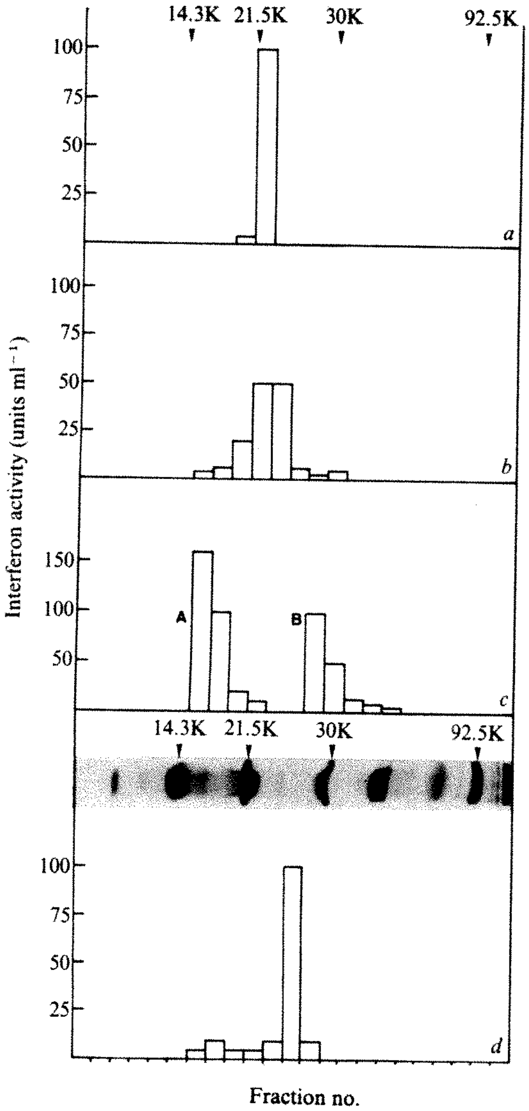

Fig. 2 Polyacrylamide gel patterns of bacterial HF–IF and authentic HF–IF. The following 100-μl samples were loaded on slots of 2 cm width: *a*, authentic HF–IF in Eagle's minimal essential medium, 10% calf serum; *b*, authentic HF–IF in control bacterial extract of M5219/pPLa8 (42 °C); *c*, bacterial extract of M5219/pPLc-HFIF-67-8 (42 °C); *d*, bacterial extract of M5219/pPLa-HFIF-67-12Δ19 (42 °C). ^{14}C-labelled protein markers electrophoresed in an equivalent amount of bacterial extract of M5219/pPLc-HFIF-67-8 (42 °C) are shown as an insertion in *d*. Bacterial extracts were prepared by treatment with SDS, β-mercaptoethanol, and urea (compare with procedure II in legend to Table 1). All samples were boiled for 1 min before electrophoresis, which was run according to Laemmli[28] in 12.5% polyacrylamide gel. IF activity profiles (*a*, *b*, *c*, *d*) were obtained after elution of successive 0.5 cm gel slices for 15 h in 500 μl of 0.5% bovine serum albumin in Tris (0.0125 M), glycine (0.096 M), 0.05% SDS followed by the antiviral IF assay (compare with legend to Table 1). Arrows with molecular weight corresponding to ^{14}C-labelled markers are indicated on top.

HF–IF is largely species specific, exhibiting little (if any) antiviral effect on heterologous cells[1]. Consistent with this property, bacterial IF showed no detectable antiviral protection on cells of monkey, feline, rabbit or mouse origin (Table 3). With respect to the feline cells, bacterial and authentic HF–IF behave differently from human leukocyte interferon.

Further evidence substantiating the presence of active HF–IF in induced *E. coli* extracts was provided by demonstrating the induction of 2', 5'-oligoadenylate (2–5A) synthetase. Kerr *et al.*[20] first reported that interferon increases the level of this enzyme in susceptible cells. As shown in Table 4, appropriate bacterial extracts were able to enhance the incorporation of [α-^{32}P]ATP in ppp5'A2'p5'A2'p5'A. The 2–5A synthetase-inducing activity of the bacterial extracts was proportional to their antiviral activity. This bacterial IF activity was likewise neutralized by anti-HF–IF antiserum.

Size estimations of bacterial HF–IF

To estimate the molecular weight of the bacterial IF activity in comparison with authentic HF–IF, bacterial extracts were fractionated by polyacrylamide gel electrophoresis in denaturing conditions and the antiviral activity determined for eluates from successive gel slices (Fig. 2). Whilst authentic HF–IF showed a single peak of activity after electrophoresis, the bacterial IF activity appeared in two different peaks. Very accurate molecular weights could not be assigned because of insufficient resolution of the gel; this was mainly due to an overloading effect

Table 2 Characterization of the bacterial HF–IF activity

The following experimental methods were used for the characterization: *a*, dialysis at neutral *p*H took place overnight at 4 °C against phosphate buffered saline (PBS). *b*, Two volumes of a saturated $(NH_4)_2SO_4$ solution were added to one volume of extract. After 30 min on ice, the pellet was centrifuged at 12,000*g* for 10 min and redissolved in PBS. *c*, The bacterial extracts were either dialysed for 15 h against glycine-HCl (50 ml, *p*H 2.2), followed by dialysis against PBS for 3 h, or acidified with HCl, followed by neutralization with NaOH. After removal of the precipitate the antiviral activity was determined. *e*, Trypsin digestion was for 1 h at 37 °C with serial dilutions of the enzyme added to the diluted extract. The lowest trypsin concentration that completely abolished the antiviral activity is indicated. *f*, The antibody neutralization assays were carried out essentially as described by Havell *et al.*[22]. About 10 IF units ml^{-1} of the preparations were incubated for 1 h at 37 °C with serial dilutions of goat anti-HF–IF antiserum, after which the residual antiviral activity was determined. Values are presented as neutralizing titres, that is, the highest dilution of antiserum which neutralized the protective effect of IF by 50% multiplied by the interferon titre of the sample assayed. Roman numerals in parentheses refer to the extraction methods described in Table 1.

Table 3 Antiviral protection of bacterial IF activity and authentic interferons

	Interferon activity (units per ml), assayed on					
	Human T-21	Human VGS	Monkey BSC-1	Rabbit primary kidney	Feline lung	Mouse L-929
M5219/pPLc-HFIF-67-8 (42 °C) (II)	3,000	300	<100	<100	<100	ND
(III)	30	<10	<10	<10	<10	ND
M5219/pPLc-HFIF-67-8 (42 °C) (II) elution peak A	2,000	200	<10	<10	<10	<10
M5219/pPLc-HFIF-67-8 (42 °C) (II) elution peak B	2,000	500	<10	<10	<10	<10
Human fibroblast interferon	3,000	500	30	30	<3	<2
Human leukocyte interferon	5,000	500	30	10	1,000	30
Human immune (type II) interferon	3,000	1,000	10	<3	<3	<2
Mouse L-929 interferon	<2	<2	<2	<2	<2	500

The antiviral activity was assayed as described in the legend to Table 1, except that the titres were directly determined from the dilution end points. T-21 are human fibroblasts trisomic for chromosome 21; VGS are normal human diploid fibroblasts[23]. Feline lung cells were obtained from Flow Laboratories (cat. no 0-10907). ND, not determined.

which resulted in a different migration of the proteins, as revealed by internal ^{14}C-labelled protein markers. Both peaks were neutralized to the same extent with anti-HF–IF antiserum (Table 2) and did not show detectable IF activity on heterologous cells (Table 3). The first peak, corresponding to an approximate molecular weight (MW) of 15,000–18,000, may have arisen by haphazard proteolytic cleavage of the fusion protein, or by limited *bona fide* processing at the now internal signal peptide, or by a combination of both processes. As shown previously, the absence of the carbohydrate moieties results in a protein which migrates in polyacrylamide gel to a position of about 4,000 MW below the authentic glycosylated HF–IF[10]. The 15,000–18,000-MW component, clearly present in *E. coli* M5219/pPLc-HFIF-67-8 extract, could also be detected at low but still significant levels in M5219/pPLa-HFIF-67-12Δ19 extracts. The second peak, with an apparent higher molecular weight, could correspond to the fused prokaryotic HF–IF polypeptide, or a slightly processed form. The tentative identification of the slower moving HF–IF activity peak as the fusion protein is strengthened by a different migration of the activity in the extract of M5219/pPLa-HFIF-67-12Δ19 (with a predicted fusion protein of about 28,000 MW) compared to the M5219/pPLc-HFIF-67-8 extract (with a predicted fusion protein of about 33,000 MW) (Fig. 2). The fusion proteins may themselves have some activity or be processed to an active product at the time when the bacterial extract (or gel eluate) is applied onto the human cells for the antiviral assay.

plus 1 n.u. per ml anti-HF–IF	29,260
plus 100 n.u. per ml anti-HF–IF	727
M5219/pPLc-HFIF-67-8 (42 °C) (I)	17,478
plus 1 n.u. per ml anti-HF–IF	12,115
plus 100 n.u. per ml anti-HF–IF	7,992
plus 10000 n.u. per ml anti-HF–IF	2,517

All samples were diluted sixfold (*a*) or tenfold (*b*) before assay. Antiviral titres (before dilutions) are given in parentheses. Neutralization with goat anti-HF–IF antiserum was at 37 °C for 1 h; n.u. neutralizing units. Roman numerals in parentheses refer to the extraction methods described in Table 1 legend. The obtained values are listed after subtraction of the endogenous background activity: 3,342 c.p.m. in *a* and 2,073 c.p.m. in *b*. The 2–5A synthetase assay was modified from Kimchi *et al.*[24] and Minks *et al.*[25]. Confluent monolayers of HeLa cells in microtitre plates (96 wells) were treated with the diluted bacterial extract or with control HF–IF for 20 h. After cooling and washing with NaCl (140 mM), Tris-HCl (35 mM, *p*H 7.5), the cultures were lysed in 5 μl (*a*) or 10 μl (*b*) of 0.5% NP40, PMSF (1 mM), NaCl (140 mM), Tris-HCl (35 mM *p*H 7.5). After shaking vigorously for 20 min at 0 °C, the lysates were collected and centrifuged for 20 min at 10,000*g*. 3.5 μl of the supernatant was incubated for 2 h at 31 °C in 6 μl of KOAc (100 mM), $Mg(OAc)_2$ (25 mM), HEPES-KOH (10 mM, *p*H 7.4), ATP (5 mM), fructose-1,6-bis-phosphate (4 mM), DTT (1 mM), poly I·C (20 μg ml^{-1}) and 2 μCi of lyophilized [α-^{32}P]ATP (400 Ci mmol^{-1}). The reaction was stopped by heating for 3 min at 95 °C and the samples were treated with 150 units ml^{-1} of calf intestine alkaline phosphatase (Boehringer) at 37 °C for 1 h. After clearing, 1 μl was spotted on PEI-cellulose thin-layer plates and chromatographed in 1 M acetic acid for 2–3 h. The plates were autoradiographed and the incorporation of ^{32}P in the 2–5A trimer was determined.

Conclusion

We have demonstrated the expression of HF–IF activity in *E. coli*. This synthesis depends on the presence of the HF–IF cDNA gene in the appropriate orientation and of the controlled induction of transcription from the P_L promoter. The antiviral activity obtained from *E. coli* is due to the presence of polypeptide(s) which for all physicochemical, biological and immunological characteristics tested closely resembles authentic HF–IF. Polyacrylamide gel electrophoresis resolved the bacterial IF activity into two different size classes; the smaller component presumably resulted from a post-translational cleavage of the fusion proteins.

The HF–IF produced in *E. coli* is still low in titre (about 100 units per 5×10^8 cells ml^{-1}), but undoubtedly this can be improved by better plasmid constructions. Thus, we hope to produce sufficient quantities of bacterial HF–IF to compare its biological and pharmacological properties with those of authentic glycosylated HF–IF and of bacterial leukocyte IF, and perhaps to evaluate its potential clinical applications.

The transforming gene (src) *of avian sarcoma virus (ASV) and adjacent regions of the viral genome have been isolated by molecular cloning of viral DNA. Their nucleotide sequence encompasses the whole of* src *and the portion of the gene* env *that encodes gp37, one of two glycoproteins found in the viral envelope.* Src *encodes a single, hydrophobic protein with structural features that conform to previous descriptions of the gene product (pp60*^{src}*). It appears that a single viral protein is responsible for both the initiation and maintenance of neoplastic transformation by avian sarcoma virus. Neither* src *nor its product bear any obvious structural relationship to several other viral oncogenes and their encoded proteins.* Src *is flanked by a repeated nucleotide sequence that may facilitate frequent deletion of the gene from the viral genome.*

VIRAL oncogenesis takes two general forms. Infection by some tumour viruses is apparently one of several successive events that combine to produce the neoplastic phenotype[1]. The precise role of the virus in this setting is an enigma. Other viruses bear genetic loci ('transforming genes' or 'oncogenes') whose expression may be wholly responsible for the transformation of infected cells[2]. Successful studies of both forms of viral oncogenesis have been carried out, but we owe much of the recent advance in our understanding of neoplastic transformation to the exploration of viral oncogenes—their action on the cell is swift and direct; they can be mutated to obtain useful conditional defects; the nucleic acids of which they are composed can be isolated and sequenced; and they act by means of proteins whose properties must underlie the mechanism of transformation.

Avian sarcoma virus (ASV) is a retrovirus that induces fibrosarcomas in infected hosts and transforms fibroblasts in culture. The genome of ASV carries a genetic locus (*src*) whose action is required for both the initiation and maintenance of neoplastic transformation[3]. Previous work has identified one product of *src*—a phosphoprotein of molecular weight 60,000 (refs 4–6) that is anchored to the cytoplasmic aspect of the plasma membrane of infected cells[7,8]. Both crude[9] and purified[10,11] preparations of pp60^{src} phosphorylate tyrosine exclusively in protein substrates, and cells transformed by ASV contain more phosphotyrosine than do uninfected cells[9,12]. These findings have engendered the hypothesis that phosphorylation of tyrosine in one or more cellular proteins is central to the mechanism by which *src* transforms cells. Important issues remain unresolved, however. Can the action of *src* alone induce neoplastic transformation? Is pp60^{src} the sole protein encoded by *src*? What is the nature of the association between pp60^{src} and the plasma membrane? Where are the phosphoamino acids located in pp60^{src}, and what is their role in the enzymatic activity of the protein? Does the phosphotransfer carried out by pp60^{src} *in vitro* reflect the activity of the protein in the infected cell? Might pp60^{src} possess functional properties other than protein kinase activity? As a step towards the resolution of these issues, we have determined the nucleotide sequence of *src* and regions adjacent to it in the ASV genome, and we have used these data to deduce a possible amino acid sequence for pp60^{src}. Inspection of the derived protein sequence permits some speculations on possible relationships between structure and function of pp60^{src}.

Experimental approach

The RNA genome of retroviruses is transcribed into duplex DNA during the early hours of infection[13]. Circular forms of retrovirus DNA can be isolated from infected cells and cloned into prokaryotic vectors[14,15]. We have described previously the use of molecular cloning to isolate a 3.1-kilobase *Eco*RI fragment of DNA (see Fig. 1) that contains the entirety of *src*, all but 65 nucleotides of c (an untranslated region that lies to the right of *src* on the genetic map of ASV; see ref. 16), and about 1.0 kilobases to the left of *src*[15,17]. We subcloned this DNA into the single-stranded DNA phage M13mp2 (ref. 16) to facilitate sequence analysis by the chain termination technique developed by Sanger and colleagues[18]. Clones representing both the positive and negative strands of viral DNA were isolated and sequenced so as to ensure the accuracy of the results. We also

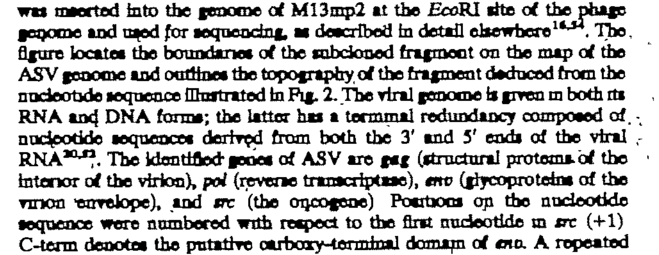

Fig. 1 The genome of ASV and the topography of the subclone used for nucleotide sequencing. A 3.1-kilobase *Eco*RI fragment of cloned ASV DNA was inserted into the genome of M13mp2 at the *Eco*RI site of the phage genome and used for sequencing, as described in detail elsewhere[16,34]. The figure locates the boundaries of the subcloned fragment on the map of the ASV genome and outlines the topography of the fragment deduced from the nucleotide sequence illustrated in Fig. 2. The viral genome is given in both its RNA and DNA forms; the latter has a terminal redundancy composed of nucleotide sequences derived from both the 3' and 5' ends of the viral RNA[20,22]. The identified genes of ASV are *gag* (structural proteins of the interior of the virion), *pol* (reverse transcriptase), *env* (glycoproteins of the virion envelope), and *src* (the oncogene) Positions on the nucleotide sequence were numbered with respect to the first nucleotide in *src* (+1) C-term denotes the putative carboxy-terminal domain of *env*. A repeated sequence described in the text is denoted as d.r., this repeat is direct, that is, it occurs in the same orientation at each position (see Fig. 3). A domain that apparently separates *env* from *src* is denoted i for intercistronic, and an untranslated region at the 3' end of the viral genome is denoted c (refs 16, 17). A possible component of the ribosome-binding site for *src* (see Fig. 3) is designated r.

0028-0836/80/380198—06$01 00

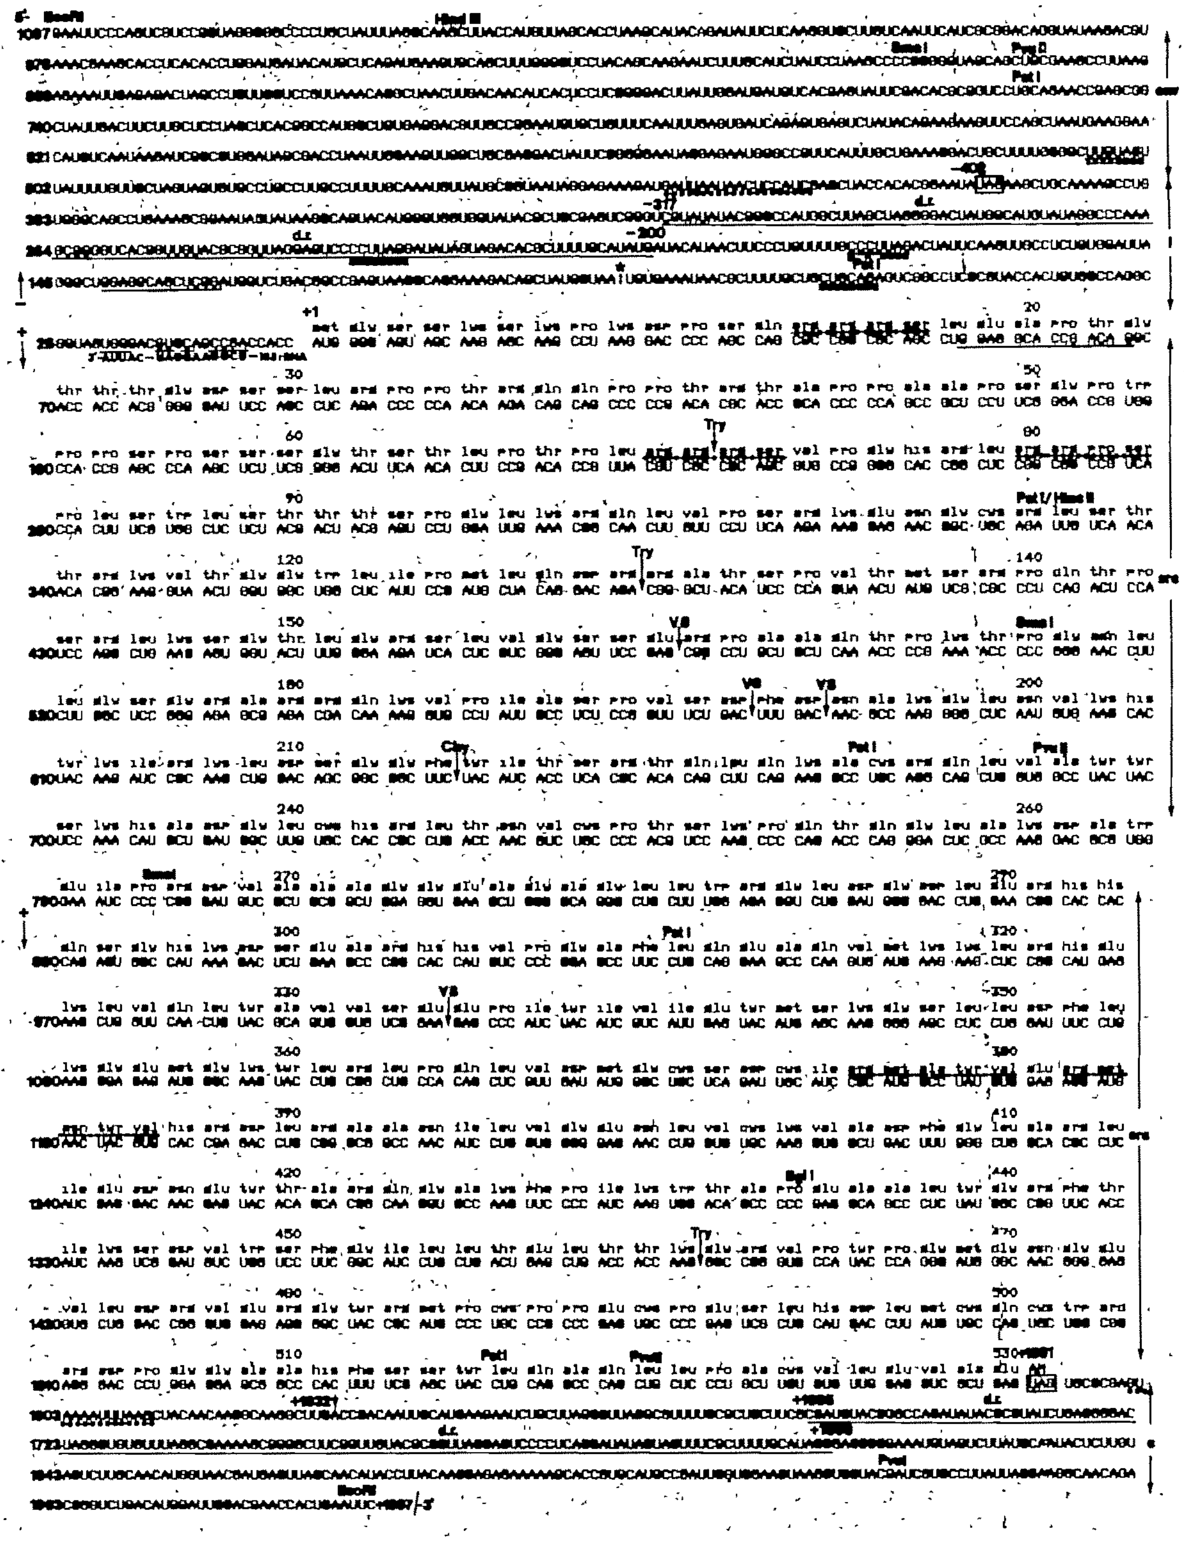

Fig. 2 The nucleotide sequence of *src* and its environs. The chain-termination technique of Sanger and colleagues[18] was used to obtain the entire sequence of both strands of the 3.1-kilobase *Eco*RI DNA fragment described in Fig. 1. Supplementary data were obtained with the procedure of Maxam and Gilbert[19]. Details have been described elsewhere[14]. We used 60 different restriction fragments derived from within the 3.1-kilobase DNA fragment as primers in the chain-termination procedure. The sequence of the DNA is displayed as the plus (sense) strand of viral RNA and is numbered according to the convention explained for Fig. 1, with position 1 being the first nucleotide in the translated frame (or frame 1); frame 2 begins with position 2, frame 3 with position 3. Ts are substituted by Us. An unidentified nucleotide at position −84 is designated by an asterisk. Position −14 is either C or T and position −353 to −352 is either AC or AGC. Also given are: the amino acid sequence encoded by the translatable frame in *src*; possible sites of cleavage by proteases predicted from previous work (ref. 53, and unpublished results of A.D.L. and S. Courtneidge) (Try, trypsin; V8, *Staphylococcus aureus* V8 protease; Chy, chymotrypsin); the locations of sites of cleavage by several widely used restriction endonucleases (all of the identifiable restriction sites can be provided on request); the location of two nearly identical amino acid sequences that each contain a residue of tyrosine (+−−−); the location of the repeated sequence noted in Fig. 1 and described in detail in Fig. 3 (———); the location of prospective phosphoserines in the amino-terminal domain of pp60^{src}, identified as described in the text (••••••); a possible component of the ribosome-binding site for *src*, identified as described by Hagenbuchle *et al.*[25]; two oligonucleotides identified previously in maps of the ASV genome[22–24] (· · · ·); possible splice-acceptor sites (= = = = =); regions homologous to sequence related to the *Alu* family[26] (— — — —); and suggested terminator codons for *env* and *src* (UAG). Numbers preceded by + or − give positions in the nucleic acid sequence; all other numbers indicate the positions of amino acids within the proposed protein sequence of pp60^{src}.

used the procedure of Maxam and Gilbert[19] to obtain supplementary data. The complete strategy for the sequencing and all data are available on request.

Authentication of the nucleotide sequence

Figure 2 illustrates the entire sequence of the 3,094 nucleotides that comprise the 3.1-kilobase pair *Eco*RI DNA fragment, displayed as the sense strand of the viral RNA. Positions within the sequence are numbered with respect to the first nucleotide in *src* (+1) (see below). The nucleotide composition of the fragment is 21.1% T, 25.7% dC, 23.4% dA, and 29,8% dG. We have a variety of reasons to believe that our nucleotide sequence for *src* and its environs is correct:

(1) We have shown elsewhere that the cloned *Eco*RI DNA fragment inserted into M13 for purposes of sequencing contained a functionally competent *src* gene[20]; hence, the structure of *src* (and by inference, the remainder of the DNA fragment) was apparently undisturbed by cloning and propagation in prokaryotic vectors.

(2) The ASV DNA from which we prepared our molecular clones has been mapped extensively by site-specific cleavage with restriction endonucleases[15,21]. The sequence illustrated in Fig. 2 contains all the sites located previously by this means. During the preparation of more than 60 primers for sequencing with the terminator technique, we identified a number of additional restriction sites; these also appear at appropriate positions in the final sequence. Figure 2 summarizes the locations of cleavage sites for several widely used restriction endonucleases. A complete catalogue of restriction sites within the 3.1-kilobase *Eco*RI fragment is available from the authors on request.

(3) The boundaries that we propose for *src* and *env* are in accord with previously developed physical maps of the ASV genome (see below).

(4) Previous analyses of the ASV genome have identified a number of T1 oligonucleotides that also appear in the nucleotide sequence reported here. Moreover, our data are in general agreement with previous, less precise efforts to locate these oligonucleotides on the ASV genome. For example, the oligonucleotide at positions −436 to −420 is contained within the carboxy-terminal domain of *env*, as suggested previously[22], and the oligonucleotide at positions +1,601−+1,612 lies just beyond the 3′ boundary of *src*, rather than within the gene[23]. Other correlations with our data include: six large oligonucleotides within *src* that were identified previously in the genome of SR-A ASV[23], and four oligonucleotides in the vicinity of the carboxy-terminus of *env*, three of which occur in the genome of the Prague-B strain of ASV, the fourth in the genome of the endogenous chicken virus, RAV-0 (ref. 24). The details of these correlations are omitted here but will be supplied on request.

(5) The proposed nucleotide sequence of *src* encodes a protein with structural features that conform to previous descriptions of pp60^{src} (see below).

Structural domains within the nucleotide sequence

Computer-assisted analysis of the sequence allowed us to identify several structural domains, which are discussed below and outlined in Fig. 1.

Positions +1−+1,590 contain a single open reading frame, initiated by AUG and terminated by an amber codon (UAG, (positions +1,591−+1,593)). We deduce that this sequence constitutes *src*: it is located in the appropriate position on the physical map of the ASV genome[17], and translation from the open frame would generate a protein with structural features that conform to previous descriptions of pp60^{src} (see below). Translation from the other two reading frames in the ^{src} domain is blocked principally by opal codons (UGA; 11 of 13 terminators in frame 2, 12 of 15 terminators in frame 3), an unusual feature not encountered in other portions of the DNA fragment. In the unlikely event that all of the 11 opal terminators were to be suppressed, a protein with a molecular weight of ~44,000 could arise from positions +599−+1,805; we have no reason to believe that this ever happens in the infected cell. Of the 16 nucleotides between positions −21 and −6, 10 can base-pair with the nucleotide sequence at the 3′ terminus of 18S ribosomal RNA (see Fig. 3). Hagenbuchle *et al.* have suggested that base-pairing of this sort may be a general feature of the sites at which translation initiates in eukaryotic cells[25]. A similar structure can be formed near the 3′ terminus of *src* (positions +1,341−+1,357), but we cannot yet attribute any specific function to this location.

Positions −1,097 to −401 also contain a single open reading frame that begins at the third base at the left end of the DNA fragment (position −1,095) and terminates with an amber codon (position −402 to −400). The other reading frames are blocked by a mixture of termination codons. We presume that this domain represents the carboxy-terminal portion of the *env* gene that encodes the glycoproteins of the ASV envelope[26]. The location of this domain on the viral genome is appropriate for *env*[17,21], and the amino acid sequence deduced from the open reading frame conforms to available information on the amino acid sequence of a protein (gp37) encoded by *env* (see below).

Positions −399−−1 are closed to translation in all reading frames and apparently constitute an intercistronic region (i in Fig. 1) that separates *src* from *env*. Notable features of this region will be discussed below.

Positions +1,594−+1,997 comprise an apparently untranslated domain previously designated as c[16,17]. We have described the sequence of this domain in detail elsewhere[16].

Miscellaneous aspects of the nucleotide sequence

Several nucleotide sequences are repeated in the untranslated regions on either side of *src*. The most striking of these is a sequence of 126 nucleotides (designated d.r. in Figs 1–3) that is repeated directly (that is, in the same orientation) with 79% fidelity at positions −317−−200 and +1,685−+1,808, and that can be extended to positions −377 and +1,632 with a fidelity of 63%.

A purine-rich sequence of 13 nucleotides occurs juxtaposed to the 3′ end of d.r. Other work has implicated this sequence in the initiation of 'plus strand' DNA synthesis by reverse transcriptase[27,28]. Similar purine-rich sequences are found 11 times at fairly regular intervals (~100–250 nucleotides) throughout the 3.1-kilobase fragment. Perhaps some of these sequences are also involved in the synthesis of plus strand viral DNA, which apparently initiates at multiple sites along the viral genome[29,30].

The 3.3-kilobase mRNA for *src*[31] is formed by joining approximately 0.36 kilobases from the 5′ end of the viral genome to a point located to the left (to the 5′ side) of the *src* gene[32,33]. From the size of the mRNA and the length of the spliced leader, we compute that the splice junction should lie about 0.5 kilobases to the 5′ side of *src*—possibly within the carboxy-terminal domain of *env*[34]. We therefore searched the appropriate regions of the 3.1-kilobase DNA fragment and found four sequences that resemble the proposed prototype (5′-PyPyNPyAG-3′) for splice acceptor sites[35]: TTGTAG at positions −509−−504 (apparently within the carboxy-terminal domain of *env*), CCTTAG at positions −232−−227 and −177−−172, and CTGCAG at positions −62−−57 (located within the i region). We have no means of implicating any of these sequences in splicing. Direct analysis of viral mRNA will be required for definitive identification of the splice junction.

Positions −140−−128 and +54−+67 resemble sequences found within the *Alu* family[36] of interspersed repeated sequences in mammalian DNA and at the origins of replication for several viral DNAs (Fig. 3). The function of these widely distributed nucleotide sequences is not known. One hypothesis suggests that they may serve as origins of DNA replication in the mammalian genome[36]. If so, their presence in the nucleotide sequence of the ASV genome may be gratuitous: retrovirus DNA probably does not function as an independent replicon and may therefore have no need for a replication origin[37,38]. Alternatively, the *Alu* sequences might participate in the

Table 1 Distribution of individual amino acids within the deduced sequence of pp60^{src}

The amino acid sequence illustrated in Fig. 2 was divided arbitrarily into domains of 60 amino acids, beginning at the amino-terminus The table gives, for each domain, the total residues of each amino acid, the sum of the hydrophobic residues (Phe, Leu, Ile, Val, Trp, Pro and Ala; Hph), the predominance of basic over acidic amino acids in each domain (computed as $b-a$; the difference between the sum of His, Lys and Arg and the sum of Glu and Asp), and the sum of the hydrophilic amino acids Ser and Thr (OH).

maturation of mRNAs[36]. We note that three of the candidate splice junctions for *src* mRNA are located in the vicinity of the *Alu*-like sequence at positions −140–−128.

The amino acid sequence of pp60^{src}

We used the nucleotide sequence of the open reading frame in *src* to deduce the sequence of the 530 amino acids contained in the encoded protein. Figure 2 illustrates the deduced amino acid sequence, and Table 1 describes the distribution of individual amino acids within the protein. Several features of the deduced structure conform to previous descriptions of pp60^{src}: the molecular weight is 58,449; the protein is hydrophobic[11]; 9 of the 12 methionines are in the carboxy half of the molecule (ref. 39, and H. Oppermann, personal communication); and the amino acid sequence can account for seven sites of specific cleavage by proteases predicted from previous work (Fig. 2). We conclude that we have probably determined the authentic amino acid sequence for pp60^{src}.

Two separate functional domains have been defined within pp60^{src} (refs 11, 40). One domain (confined to a molecular weight of ~15,000 at the amino-terminus of the protein) anchors the protein to the cytoplasmic aspect of plasma membrane, the other domain protrudes from the membrane and carries the protein kinase activity. These functional domains have apparent correlates in the composition of pp60^{src} (see Table 1): Pro, Arg, Ser and Thr are concentrated in the amino-terminal domain, Cys, Met and Tyr in the carboxy-terminal domain. Most of the protein (and the amino-terminal half in particular) is basic, whereas the carboxy-terminal domain is relatively acidic. We presume that the one-dimensional topography of pp60^{src} described here has its counterparts in the three-dimensional configuration of the protein (which we already know to be a highly elongated molecule—frictional coefficient 1.4; see ref. 5). It seems that the protein was designed on the one hand for tethering to the plasma membrane, and on the other for enzymatic activity beyond the confines of the membrane.

Using conventional procedures[41], we have deduced general features for the possible secondary structure of pp60^{src}. The central portion of the molecule (amino acid residues 221–438) is likely to be in the α-helical configuration; the carboxy-terminal domain seems to be composed of alternating α-helices and β-pleated sheets; and the amino-terminus is probably mainly β-sheet.

The portion of pp60^{src} that is anchored to the plasma membrane contains one (or more) residues of phosphoserine[6,9],

Relatively abundant codons are indicated by the arrowheads.

the exposed (kinase) domain contains phosphotyrosine[9]. We have attempted to identify the possible locations of these phosphoamino acid sequences in the deduced amino acid of pp60^{src}. Phosphoserines in other proteins are usually found in the following general structure: basic amino acid–basic amino acid–any amino acid–phosphoserine[42]. Three serine residues (17, 73 and 83) in the amino-terminal domain of pp60^{src} satisfy this criterion. Two tyrosine residues in the carboxy half of the sequence (379 and 385) are situated within virtually identical microenvironments (Arg-Met-X-Tyr-Val, where X is either Ala or Asn) that are separated by a single amino acid (Glu). We speculate that this unlikely repetition of amino acid sequence might denote the position(s) of phosphotyrosine in pp60^{src}.

Codon usage in *src*

Table 2 illustrates the prevalence of various codons for each of the amino acids in the translated frame of *src*. Relatively strong biases for particular codons were observed in several instances: CUC and CUG for Leu; UGC for Cys; AUC for Ile; GUG for Val; CAG for Gln; GAG for Glu; UAC for Tyr; CGG and CGC for Arg; and GGC and GGG for Gly; AAG for Lys. U and A are used relatively infrequently in the third position with the exception of the codons for Thr and Pro.

A possible amino acid sequence for the carboxy-terminal domain of viral glycoprotein

The *env* gene of ASV encodes two glycoproteins (gp85 and gp37) which originate from the cleavage of a single polypeptide precursor and remain linked to one another by disulphide bonds[26]. The proteins are arranged 5′-gp85-gp37-3′ on the gene. It seems possible that we have obtained the sequence of 697 nucleotides at the 3′ end of *env*, or 231 amino acids extending leftward from the carboxy-terminus of gp37 (Fig. 4). Hunter and his colleagues have identified eight amino acid residues in the amino-terminal region of gp37 of the Prague-B ASV, a different strain of ASV (E. Hunter, personal communication). Four of the identified residues occur at appropriate positions in the sequence proposed by Fig. 4: Thr at position 43, Asp at positions 47 and 48, and Glu at position 53 (residues 2, 6, 7 and 12, respectively, in the amino acid sequence, from E. Hunter *et al.*, personal communication). The codons for two other residues could be generated by changes in single nucleotides, converting Cys to Gly at position 50 in Fig. 4, and Ser to Ala at position 51. These correlations suggest that the amino acid sequence illustrated by Fig. 4 includes the entirety of gp37, whose amino-terminus would be located at residue 42 in Fig. 4, and whose un-glycosylated molecular weight would be 20,500. The carboxy-terminus of the deduced protein is exceptionally hydrophobic (37 of 43 amino acids, as noted in Fig. 4). This feature might denote a portion of gp37 that is embedded in the lipoprotein envelope of the virus and anchors the entire glycoprotein to the virion[43]. The prevalences of individual codons used to encode this protein are very different from those found for *src* (Table 3). Data presented elsewhere suggest that *src* and *env* had independent and very different evolutionary origins[44,45]. The disparities in codon usage between the two genes may reflect their distinct origins.

Comparison of *src* with other viral oncogenes

Genetic loci responsible for neoplastic transformation of infected cells have been identified within the genomes of Moloney murine sarcoma virus, polyoma virus, SV40 virus and several strains of adenovirus (see ref. 2 for reviews). We have compared the available nucleotide sequences of these loci with the sequence of *src*, and the amino acid sequences of the encoded proteins with pp60^{src}. The nucleotide sequence of *src* bears little resemblance to the sequences of the other viral oncogenes, with the exception of a few oligonucleotides (the largest being nonamers) shared with the gene for the middle T antigen of polyoma virus. We found no appreciable homology among the various amino acid sequences, although pp60^{src}, the T antigen of polyoma, and two proteins encoded in the *E1b* region of adenovirus DNA are all relatively rich in proline (data not shown).

Further comments

Src is frequently deleted during the propagation of most strains of ASV[3]. The mechanism that facilitates this deletion has not been elucidated. We propose that the large repeated nucleotide sequence (d.r.) that flanks *src* might mediate deletion of the gene, for example, by homologous recombination within the viral genome[46]. This proposal can be tested by analysing the sequence that remains at the site of the deletion subsequent to the loss of *src* (work in progress).

The direct determination of amino acid sequence remains a relatively arduous and demanding procedure, despite recent technical advances in sensitivity and convenience[47]. It seems likely that the nucleotide sequence presented here provides the authentic amino acid sequence of pp60^{src} in advance of any direct sequencing of the protein. At least one issue remains controversial, however—the claim that a portion of pp60^{src} (presumably, a terminal 'signal sequence') is removed by membrane-bound protease(s) subsequent to synthesis of the protein[48]. The issue can probably be resolved by identification of a few of the amino acids at the amino-terminus of the mature protein and comparison of these results with the nucleotide sequence of *src*. We note that amino-terminal signal sequences generally have hydrophobic domains rich in leucine[49], features not found in the amino-terminal region of the sequence of *src* (see Fig. 2).

The amino acid sequence deduced here for pp60^{src} suggests that the protein is hydrophobic (average hydrophobicity of 1.1, computed as described in ref. 50). This property is in accord with previous findings that pp60^{src} is an integral protein of the plasma membrane, can be released from the membrane only by treatment with detergents, and is more soluble in aqueous solutions when detergent is present[11]. A more detailed analysis of the

Fig. 4 A possible amino acid sequence for the carboxy-terminal domain of the glycoprotein of ASV. An amino acid sequence was deduced from the nucleotide sequence illustrated in Fig. 2, beginning with position −1,095 and ending before the amber codon at positions −402–−400. The amino acid sequence is given in terms of the conventional single-letter symbols. The underlining demarcates an exceptionally hydrophobic region. The arrow denotes the presumptive amino-terminus of gp37.

amino acid sequence has revealed two relatively isolated hydrophobic domains at residues 52–57 (average hydrophobicity 2.2) and 121–126 (average hydrophobicity 2.4) (data not illustrated). Both domains are located near the amino-terminus of the molecule where the protein apparently inserts into the plasma membrane[8,40].

The nucleotide sequence reported here substantiates previous assumptions that *src* encodes a single protein. Transfection of the 3.1-kilobase DNA fragment containing *src* into mammalian cells leads to the synthesis of pp60^{src} and the neoplastic transformation of recipient cells[19,51]. Moreover, the transformed cells are tumorigenic in newborn allogeneic animals (unpublished results of H. Oppermann and P. Luciw). We can now rigorously conclude that *src* is the only viral gene required for tumorigenesis by ASV, and that the mechanism of neoplastic transformation by the virus derives entirely from the biochemical properties of pp60^{src}.

Chemical analysis of pp60^{src} and site-specific mutagenesis of *src* will be used to identify the sites of functionally important modifications (such as phosphorylation) within the protein, to locate the active site for phosphotransfer by the protein, and to describe other important features of the protein. These efforts will require the nucleotide sequence of *src* and the amino acid sequence of pp60^{src}.

We thank E. Hunter for his unpublished data on the amino acid sequence of gp37, I. Verma for providing the nucleotide sequence of Moloney murine sarcoma virus *src*, B. Delorbe, R. Parker, P. Luciw and B. Baker for gifts of cloned DNA, J. Messing for providing phage and bacterial strains, H. Martinez for the use of his computer program and for assistance with computerized analysis of nucleotide sequences, J. Shine, R. Swanstrom, J. Majors, L. Levintow, S. Courtneidge and H. Oppermann for helpful discussions and unpublished results, and B. Cook for stenographical assistance. This work was supported by grants from the NCI and the American Cancer Society.

Note added in proof: After preparing this manuscript, we learned of the identification of several new avian sarcoma viruses with transforming genes distinct from *src*. It is now more accurate to designate the virus studied here as Rous sarcoma virus, Schmidt–Ruppin strain—one of several isolates that share closely related *src* genes.

DNA *N*-glycosylases and UV repair

Bruce Demple & Stuart Linn

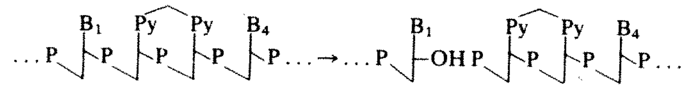
Department of Biochemistry, University of California, Berkeley, California 94720

Repair of some DNA photoproducts can be mediated by glycosylic bond hydrolysis. Thus, Escherichia coli *endonuclease III releases 5,6-hydrated thymines as free bases, while T4 UV endonuclease releases one of two glycosylic bonds holding pyrimidine dimers in DNA. In contrast, uninfected* E. coli *apparently does not excise pyrimidine dimers via a DNA glycosylase.*

DAMAGED bases can arise in DNA by a number of routes. These include spontaneous hydrolysis as in the deamination of cytosine[1] or adenine[2], reaction with such chemical agents as monofunctional alkylating agents[3], and radiation.[4] Two major routes for repair of damaged DNA have been proposed for *Escherichia coli*, initiated by strand breakage near the damage[5], or by specific hydrolysis of the glycosylic bond of a non-conventional base[6]. Using repair of pyrimidine dimers produced in

0028-0836/80/380203—06$01.00

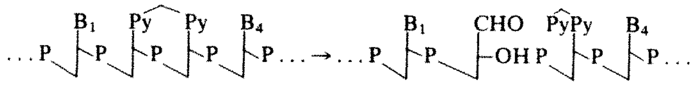
DNA by UV irradiation as a model system, a sequence of repair initiated by phosphodiester bond hydrolysis has been proposed[7]. In this scheme, the initial, perhaps rate-limiting step is endonuclease incision, mediated by enzymes specific for pyrimidine dimers as follows:



(1)

Excision of the damage is then carried out by an exonuclease, with DNA polymerase and DNA ligase restoring the integrity of the genetic material. Considerable attention has been directed recently toward the alternative pathway initiated by glycosylic bond hydrolysis. Four enzymes have been reported in *E. coli* which remove, respectively, uracil[6], hypoxanthine[2], 3-alkyladenine[8] or formamidopyrimidine[9]. This base excision results in the formation of apurinic or apyrimidinic (AP) sites, which could then be repaired by action of AP endonuclease, DNA polymerase and polynucleotide ligase.

Recently, Grossman and his colleagues presented evidence suggesting that UV endonuclease from *Micrococcus luteus* actually cleaves the phosphodiester bond between the nucleotides of a pyrimidine dimer[10]. This assertion was based on results of gel electrophoresis of a short fragment of UV-irradiated DNA incised by UV endonuclease. Products were observed which appeared to correspond to incision within the pyrimidine dimers. However, when these same fragments were heated at 100°C or exposed to alkali, they exhibited mobility corresponding to a strand cut immediately 5′ to the pyrimidine dimer. This alkali- and heat-lability was similar to that observed for AP sites, and these authors interpreted their results to indicate that UV endonuclease cleavage occurs as follows:



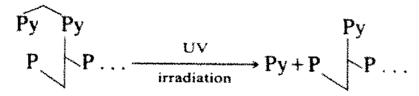
(2)

Thus, an AP deoxyribose is left at the 3′ terminus of the nick and could be removed by heat or alkali to yield a DNA fragment shorter by apparently one nucleotide. This interpretation contrasted with previous models in which phosphodiester bond hydrolysis is the first step in the repair pathway and would result in cleavage 5′ to the dimer rather than within it. We wished to examine which mechanism might apply to the UV endonuclease induced by infection of *E. coli* with bacteriophage T4. Like the *Micrococcus luteus* UV endonuclease, the T4 enzyme appears to be specific for pyrimidine dimers[11] and might well act by a similar mechanism.

In addition, we tested whether *E. coli* endonuclease III acts as a glycosylase followed by an AP endonuclease, since we had previously observed it to cleave two apparently unrelated substrates: DNA containing 5,6-dihydroxydihydrothymine and DNA containing AP sites[12].

T4 UV endonuclease has pyrimidine dimer glycosylase activity

We recently have taken advantage of the requirement of *E. coli* DNA polymerase I for a 3′-hydroxyl nucleotide terminus to probe the structure of endonuclease products[13]. In those experiments it was shown that the UV endonuclease controlled by phage T4 (gene *v*) acts on UV-irradiated DNA to form nicks containing an AP deoxyribose at the 3′ terminus. Such a structure could arise by hydrolysis of the glycosylic bond of the 5′ pyrimidine nucleotide of the dimer, as proposed by Grossman *et al.*[10] for the UV endonuclease from *M. luteus* (see above). The resulting pyrimidine dimer nucleotide at the 5′ terminus would have an important feature: if the cyclobutane bonds of the dimer could be broken by additional UV irradiation (as demonstrated for free thymine dimers in aqueous solution[14]), one pyrimidine would be released as the free base from each such structure. Concomitantly, a normal pyrimidine nucleotide would be left at the 5′ terminus:



(3)

Thus, photolytic release of pyrimidine bases after treatment of UV-irradiated DNA with UV endonuclease could provide a rapid and specific assay for this unusual structure and for the action of a putative pyrimidine dimer-DNA glycosylase.

As seen in Fig. 1, incubation of UV-irradiated, ^{3}H-thymidine-labelled DNA with T4 UV endonuclease did not of itself result in the release of free thymine. However, secondary irradiation of such enzyme-treated DNA did release free thymine base. The amount of base which could be released was a function of the primary dose to which the DNA was exposed; prolonged incubation with excess UV endonuclease did not increase the amount of free thymine formed. High pressure liquid chromatographic analysis of the products of a limit reaction did not

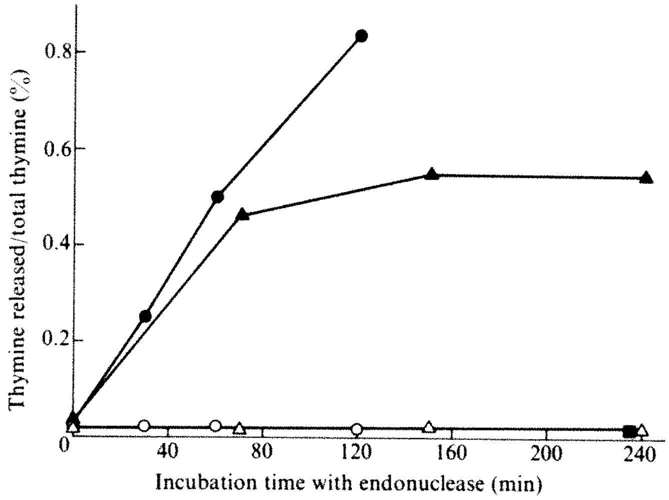


Fig. 1 Generation of photo-releasable thymine by T4 UV endonuclease. T7 ^{3}H-DNA (25,000–29,000 c.p.m. per nmol nucleotide), prepared as described by Richardson[30], was irradiated on ice under a Westinghouse germicidal lamp (G15T8) at a dose rate of $3\ \mathrm{J\ m^{-2}\ s^{-1}}$, as determined by potassium ferrioxalate actinometry[31]. Irradiation was for 0 min (square), 10 min (triangles, 1.35 mM DNA-nucleotide), or 20 min (circles, 0.58 mM DNA-nucleotide). DNAs were then incubated at 37 °C for times indicated in 140 µl reactions containing 25 mM potassium phosphate, *p*H 7.4–1 mM EDTA–0.2 M NaCl–80 µg ml^{-1} BSA, 17 nmol DNA-nucleotide and enzyme [8.4 µl per sample (squares, triangles) or 5.3 µl per sample (circles)]. After chilling, a second 20-min irradiation was carried out under conditions of the primary irradiations (>90% of maximum photorelease) (solid symbols). Samples were then assayed for thymine base by high pressure liquid chromatography (triangles) or by Dowex 1 chromatography (circles). For high pressure liquid chromatographic analysis samples were diluted to 300 µl with water and precipitated by addition of 30 µl of 1 mg ml^{-1} *Bacillus subtilis* DNA and 900 µl 100% ethanol. After 10–30 min at −70 °C samples were spun for 5 min in a Beckman Microfuge. The supernatants were concentrated by evaporation, then mixed with 15 µl of 7.5 mM thymine and water added to a final volume of 350 µl. A 100-µl portion of each sample was then injected into a Waters model ALC/GPC 244 liquid chromatograph with C-18 reverse phase column (25 cm by 4.6 mm internal diameter) equilibrated with 2.5 mM potassium phosphate–2.5% methanol, *p*H 3.0[32]. Flow rate was 2 ml min^{-1} at 1,500 p.s.i. The first 3 ml was collected as a single fraction; subsequent fractions were 0.3 ml. After determining the absorbance of the fractions at 254 nm to identify the thymine location, Triton X-100/toluene-based fluor was added to each and the ^{3}H radioactivity determined. For thymine determination by Dowex 1 chromatography[33], samples diluted to 300 µl with water were precipitated by addition of 100 µl 10 mg ml^{-1} BSA and 500 µl 7% TCA, and centrifugation. The supernatants were extracted twice with 13 vol. cold diethyl ether to remove TCA, and residual ether was removed under a stream of N_2, after which each sample was made to 1,100 µl with water and 11 µl 1 M Tris-HCl, *p*H 7.5. One ml of each sample was then applied to a 1 ml column of Dowex 1-X8 equilibrated with 10 mM ammonium formate, *p*H 4.2. The columns were washed with 5 ml of this same buffer in 1 ml aliquots, and 1 ml fractions were collected directly into scintillation vials and the radioactivity determined. T4 UV endonuclease was prepared as described by Friedberg and King[34], except that the DNA-cellulose fraction was stored at −20 °C in 50% glycerol containing 5 mM potassium phosphate, *p*H 7.0–0.5 mM dithiothreitol–5% ethylene glycol. Enzyme stored in this manner retained full activity after 2 yr.

Table 1 Generation of photo-releasable thymine and nicks by T4 UV endonuclease

Endonuclease incubation (min at 37 °C)	Secondary UV irradiation	Free thymine (pmol)	Total nicks (pmol)
0	–	<1	0.4
	+	<1	0.4
30	–	<1	2.0
	+	2.9	—
60	–	<1	4.2
	+	5.3	3.5
120	–	<1	*
	+	9.6	*

T7 ^{3}H-labelled DNA (0.57 mM, 40,600 c.p.m. per nmol nucleotide) was irradiated with 1,800 Jm^{-2} UV light. Photo-released thymine formed by T4 UV endonuclease was measured by Dowex 1 chromatography as described in Fig. 1 legend. Nicking of the T7 DNA was determined by sedimentation in 5% to 20% sucrose gradients containing 0.25 M NaOH–5 mM EDTA for 210 min at 49,000 r.p.m. in a Beckman SW 50.1 rotor. Average molecular weights were calculated according to Studier[38] and used to determine the average number of nicks per T7 genome. Total nicks of 2 pmol correspond to 9.5 nicks per T7 genome.

* Too numerous to quantify.

detect any labelled base, nucleoside or nucleotide other than thymine with or without the second irradiation (data not shown).

The UV-irradiated DNA was also analysed for the number of nicks produced by UV endonuclease (Table 1). The number of nicks introduced during the enzyme incubation was approximately equal to or somewhat less than the amount of thymine releasable by the secondary irradiation. This near-equality might imply simultaneous action of the DNA glycosylase activity and phosphodiester bond cleavage. However, we have shown previously[13] that, in an enzyme-limited reaction, T4 UV endonuclease acting on UV-irradiated DNA transiently creates sites which are sensitive to AP endonuclease. For T4 UV endonuclease therefore, pyrimidine dimer-DNA glycosylic bond cleavage appears to precede phosphodiester bond cleavage.

Pyrimidine dimers excised *in vivo* by uninfected irradiated *E. coli* are not in the form of pyrimidine dimer nucleotides

We also tested whether the excision of pyrimidine dimers in uninfected *E. coli* cells might be mediated by an *N*-glycosylase activity. Since the literature is unclear with respect to the properties of the enzyme(s) controlled by the *uvr*A, *uvr*B and *uvr*C loci[15,16], we chose to examine the structure of the products excised by this system *in vivo* from the DNA of irradiated cells. Setlow and Carrier[17] and Boyce and Howard-Flanders[18] have shown that pyrimidine dimers removed from the DNA of irradiated *E. coli* are contained in acid-soluble oligonucleotides which are retained in the cells. If this excision process is indeed mediated by hydrolysis of the glycosylic bond of one pyrimidine of the dimer, these oligonucleotides would be expected to contain the pyrimidine dimer nucleotide structure, which could be identified by its UV-dependent release of pyrimidine bases.

We therefore extracted acid-soluble oligonucleotides from cells that had been irradiated and then incubated for 3 h in growth conditions, during which 70% of the dimers were excised from the cellular DNA. Secondary irradiation of these oligonucleotides, however, did not release significant amounts of free thymine (Table 2). If the dimers in this material had each retained but a single glycosylic bond, half of the label measured in dimers should have been released as free thymine—2.2% of the total thymine for the sample shown. Instead, a UV dose which released thymine from essentially all of the dimers acted upon *in vitro* by T4 UV endonuclease yielded less than one-tenth of the 2.2% value. As a control for pyrimidine dimers retaining both glycosylic bonds, oligonucleotides were generated by pancreatic DNase digestion of DNA irradiated *in vitro*. This material (Table 2, sample 3) did not contain significant photoreleasable thymine. On the other hand, irradiated DNA which had been treated with excess T4 UV endonuclease prior to the pancreatic DNase digestion gave rise

Table 2 Test for photo-releasable thymine in excision products of UV-irradiated *E. coli*

Sample	Secondary UV irradiation ($J m^{-2}$)	Thymine in dimers (% total thymine)	Free thymine base (% total thymine)
(1) Acid-soluble fraction from irradiated, non-incubated cells	0	<0.01	0.33
	3,600	ND	0.35
(2) Acid-soluble fraction from irradiated, incubated cells	0	4.4	0.51
	3,600	2.5	0.68
(3) DNase I digest of irradiated T7 DNA, acid-soluble fraction	0	1.8	0.02
	3,600	5.9	0.05
(4) DNase I digest of irradiated, T4 UV endonuclease-treated T7 DNA, acid-soluble fraction	0	2.2	0.09
	3,600	6.2	1.11

E. coli AB1157 was grown for 3 generations to 10^8 cells per ml in 100 ml K medium with 200 μg ml^{-1} deoxyadenosine and 5 μCi ml^{-1} ^{3}H-thymidine (Amersham, 15 Ci $mmol^{-1}$). K medium contains per litre: 1 g NH_4Cl, 6 g Na_2HPO_4, 3 g KH_2PO_4, 10 g glucose, 10 g vitamin-free casaminoacids, 0.2 mg thiamine, 24 mg $MgSO_4$ and 2 mg $CaCl_2$. Cells were collected and washed 5 times by centrifugation using 25 ml 0.1 M NaCl–10 mM Tris, *p*H 7.5 (NT buffer). The final pellet was suspended in 225 ml NT buffer and aliquots of 28 ml were each irradiated at 2 J m^{-2} s^{-1} for 30 s in a 15 cm glass Petri dish with mixing, then returned immediately to ice. Cells were collected by centrifugation and 1/4 of the irradiated cells was suspended in 1 ml 10 mM Tris, *p*H 7.5, and the remainder was suspended in 25 ml NT buffer and added to a flask containing 50 ml K medium. The flask was covered with foil to prevent photoreactivation and incubated for 3 h at 37 °C with shaking. After incubation, the cells were collected by centrifugation, washed twice with 25 ml NT buffer, then suspended in 1 ml 10 mM Tris, *p*H 7.5. An equal volume of cold 10% trichloracetic acid (TCA) was then added to each cell suspension and, after mixing, incubated 10 to 15 min on ice. Acid-insoluble material was removed by centrifugation for 10 min at 10,000 g. The supernatants were extracted 3 times with 5 volumes of ice-cold diethyl ether. Remaining ether was removed with a stream of N_2. Free thymine in the acid-soluble extract of the incubated cells (1–2% of total ^{3}H) was reduced by chromatography on DEAE-cellulose (Brown & Co., Berlin, New Hampshire). A sample (1.2 ml, 2×10^5 c.p.m.) was diluted 5-fold with 10 mM Tris, *p*H 7.9 and applied at about 3 ml per h to a 3-ml column of DEAE-cellulose equilibrated with this same buffer. The column was washed with 5 ml of buffer and eluted with 10 ml of 0.5 M NaCl–9 mM Tris, *p*H 7.9 while 0.5 ml fractions were collected at 2 ml per h. Fractions containing about 98% of the applied radioactivity (3.0 ml) were pooled and evaporated to dryness at 35 °C. This material was redissolved in 300 μl distilled water and applied to a 0.7-cm × 38-cm column of Sephadex G10 equilibrated with 5 mM Tris, *p*H 8.2. Washing with this buffer was continued at 3 ml per h and 0.5-ml fractions collected. Radioactivity in the fractions was determined by scintillation counting, while NaCl was detected by conductivity measurement. More than 90% of the applied material was recovered free of NaCl and used for subsequent studies. Fifty-five μl T7 DNA (0.57 mM-nucleotide, 40,000 c.p.m. per nmol-nucleotide) was irradiated for 300 s at 3 J m^{-2} s^{-1} 254 nm light and 25 μl aliquots made up with stock reagents to 240 μl T4 UV endonuclease cocktail (see legend to Fig. 1). Thirty μl T4 UV endonuclease (33 fmol glycosylic bonds hydrolysed per min per μl) or 30 μl T4 UV endonuclease storage buffer were added and incubation carried out for 6 h at 37 °C. Endonuclease was inactivated by heating for 3 min at 70 °C and glycerol removed from the samples by dialysis against 1 litre of 10 mM Tris, *p*H 7.9. One-twentieth volume of 1 M Tris-HCl, *p*H 7.9 and 0.01 volume of 1 M $MgCl_2$ were then added to each sample, followed by 30 μl of 2 μg ml^{-1} pancreatic DNase (Millipore). Digestion was carried out for 4 h at 37 °C and the reaction mixes chilled on ice. Following this 170 μl 10 mg ml^{-1} bovine serum albumin and 830 μl 7% TCA were added to each sample, followed by mixing and 10–15 min incubation on ice. Acid-insoluble material was removed by centrifugation and the acid-soluble supernatants (containing 65–70% of the total radioactivity) extracted 3 times with 8 volumes of cold diethyl ether. After removal of remaining ether with a stream of dry N_2, 0.01 volume of 1 M Tris, *p*H 8.2 was added to each sample and the samples stored at 0 °C. A secondary irradiation of the extracts was performed as in the legend to Fig. 1. Determination of thymine-containing pyrimidine dimers was by the method of Goldman and Friedberg[39]. Determination of photoreleased thymine by thin layer chromatography was on polyethyleneimine-cellulose plates (Brinkman) in *n*-butanol–acetic acid–water 40:6:15.

to oligonucleotides exhibiting a definite photorelease of labelled thymine (Table 2, sample 4). In uninfected *E. coli*, therefore, excision of pyrimidine dimers is apparently not mediated by a pyrimidine dimer-DNA glycosylase.

The fraction of thymine in dimers decreased during the secondary irradiation of the excision products (Table 2, sample 2), while it increased in the DNase digests (Table 2, samples 3 and 4). Chromatography on DEAE-paper indicated that the label in the digests was mainly in species larger than trinucleotides; in contrast, tritium in the excision products was primarily in the form of dTMP, as originally observed in ref. 17. Since 254 nm light catalyses an equilibrium in which less than one-fourth of the adjacent pyrimidines are dimerized[19], and since in these excision products the adjacent pyrimidines are initially largely dimerized, the proportion of dimers is expected to be reduced by the secondary irradiation. On the other hand, the oligonucleotides of the DNase digests are longer and thus would be expected to have a substantial number of non-dimerized adjacent pyrimidines. In this case, therefore, one expects an increase in the dimer content upon additional irradiation.

5,6-Hydrated thymine residues are removed by DNA glycosylase activity of endonuclease III

Exposure of DNA to UV light or other ionizing radiation produces thymine bases saturated in the 5,6-double bond[20]. Systems for repairing these lesions have been shown to be present in various organisms[20,21], including *E. coli*[22]. An enzyme, endodeoxyribonuclease III, has been isolated from *E. coli* and cleaves DNA which has been heavily UV-irradiated[23]. Characterization of extensively purified endonuclease III indicated that it recognizes lesions other than pyrimidine dimers[12]. Treatment of DNA with osmium tetroxide rendered it especially susceptible to the enzyme, suggesting that the 5,6-dihydroxydihydrothymine residues so formed are the sites of action of endonuclease III. Remarkably, endonuclease III is also highly active in cleaving partially depurinated DNA[12]. A simple hypothesis to explain the varied activities of endonuclease III is that it might contain both DNA glycosylase activity specific for 5,6-hydrated thymine and AP endonuclease activity.

Since UV light produces many lesions in DNA[4], DNA-glycosylase activity of endonuclease III was tested by analysing the products of reaction of the enzyme with ^{3}H-thymine-labelled DNA treated with osmium tetroxide (Fig. 2). Tritium label was recovered as free 5,6-hydrated thymine in amounts dependent upon the level of oxidation. High pressure liquid chromatographic analysis of a sample after extensive incubation showed the presence of tritium only in positions of authentic 5,6-dihydroxydihydrothymine and to a lesser extent in that of 5,6-dihydrothymine (Table 3). Furthermore, analysis of the extent of nicking of the DNA by alkaline sucrose gradient sedimentation indicated that the number of endonucleolytic incisions is equal to or somewhat less than the number of base molecules released by the enzyme (Table 3). At early times the formation of nicks seemed to lag behind the release of damaged bases. Thus it seems that endonuclease III acts first by cleaving the glycosylic bond of a 5,6-hydrated thymidylate residue and then by cutting the phosphodiester chain at the resultant apyrimidinic site. It is noteworthy that the 5,6-dihydrothymine did not appear to be formed by OsO_4 treatment (Table 3). Instead, it may have been introduced during the preparation of the DNA or may have been formed during DNA storage.

Table 3 Comparison of base release and nicking by *E. coli* endonuclease III

DNA treatment	Endonuclease incubation (min at 37 °C)	Free hydrated thymine released (pmol)		Nicks present (pmol)
		Dihydroxy-dihydrothymine	Dihydro-thymine*	
None	0	<0.2	<0.2	1.9
	120	<2.1	3.0	3.1
0.054% OsO_4	0	<2.3	0.2	2.0
	60	16	1.0	11
	120	18	1.3	16
0.52% OsO_4†	0	12.8	<0.02	8.3
	60	120	<0.02	63
	120	130	<0.02	>72

Base release was determined by HPLC and OsO_4 treatment was carried out as described in the legend to Fig. 2. Nicking of the DNA was determined as described in the legend to Table 1. Endonuclease reactions were as described in the legend to Fig. 2.

*Assuming specific radioactivity is that of the DNA thymine, not the undiluted label used during cell growth.

†Values are normalized from 0.27 to 0.48 pmol T7 DNA genomes as used in untreated and 0.054% OsO_4 experiments.

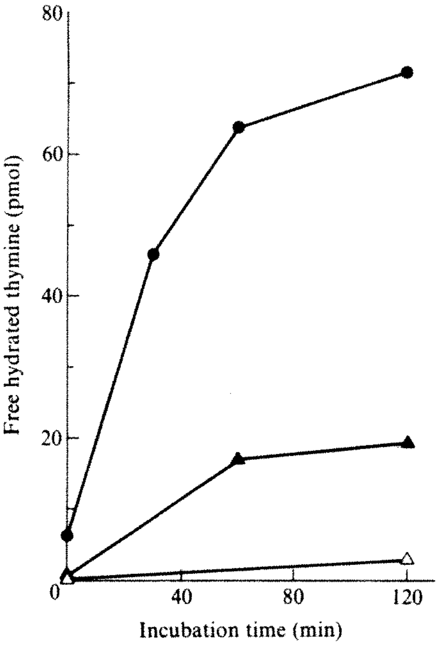

Fig. 2 Release of 5,6-hydrated thymine from OsO_4-oxidized DNA by endonuclease III. Endonuclease III was prepared as described by Gates and Linn[12]. DNA was treated with osmium tetroxide by mixing 190 μl T7 ^{3}H DNA (1.35 mM nucleotide, 25,000 c.p.m. nmol^{-1}) with 255 μl 0.3 M potassium phosphate, *p*H 12.3 and 70 μl 4% aqueous solution of OsO_4 (Polysciences) (circles) or with 190 μl 0.3 M potassium phosphate, *p*H 12.3 and 5 μl 4% aqueous OsO_4 (solid triangles). After 30 min at room temperature 195 μl 1 M potassium phosphate, *p*H 4.0 were added and unreacted OsO_4 extracted twice with 20 vol. of cold diethyl ether[35]. Remaining ether was removed with N_2 and the DNA reannealed as described by Davis and Hyman[36]. The DNA was then dialysed against 10 mM Tris, *p*H 7.5 at 4 °C, EDTA was added to 1 mM, and the solution was concentrated under vacuum. The concentrate was dialysed against 10 mM Tris, *p*H 7.5 and stored frozen at −20 °C for no longer than 2 days before use. Enzyme reaction mixtures contained 20 nmol (circles) or 38 nmol (triangles) of DNA nucleotide in 67 mM Tris, *p*H 8.2–25 mM KCl–0.005% Triton X-100, with enzyme or buffer added to a final volume of 300 μl. After incubation at 37 °C for the indicated times, samples on ice were precipitated and analysed by HPLC as in Fig. 1 legend, except that carrier 5,6-dihydroxydihydrothymine and 5,6-dihydrothymine (Sigma) were added, and 150 μl fractions collected at 1 ml min^{-1} flow rate, 730 p.s.i. Water (150 ml) was added to each fraction and the absorbance at 254 nm determined prior to scintillation counting as for Fig. 1. 5,6-dihydroxydihydrothymine was made by OsO_4-treatment of thymine[35] (Sigma) or by the method of Cadet and Teoule[37]. Open triangles, untreated DNA; solid triangles, DNA exposed to 0.054% OsO_4; circles, DNA exposed to 0.52% OsO_4.

AP endonucleases associated with T4 UV endonuclease and endonuclease III

Given that purified *M. luteus*[24] and T4 UV endonucleases[13] and *E. coli* endonuclease III each contain both DNA glycosylase and AP endonuclease activities, one may ask whether the two activities in some or all of these preparations are properties of a single enzyme. Alternatively, the presence of two activities in such preparations might be an artefact of purification and assay procedures: since endonucleolytic activity was being used as an assay in each case, AP endonuclease needed to be present in order to monitor *N*-glycosylic base removal as strand breakage.

However, there is some evidence against this possibility. With endonuclease III, the ratio of UV to AP endonuclease activity is constant during inactivation of the enzyme by both heat and storage, and the reaction optima for both activities are about the same. Similarly, T4 UV endonuclease loses both UV and AP endonuclease activities at the same rate during storage (data not shown). In addition, attempts to separate AP endonuclease from 5,6-hydrated thymine glycosylase activities have failed, and endonuclease III activity is not altered by isoelectric focusing[23]. Such studies have not been reported for the UV endonuclease of *M. luteus*; nevertheless, the cleavage products of the AP endonuclease activity of that enzyme are like those of endonuclease III and T4 UV endonuclease; that is, nicks containing a 3′-terminal AP deoxyribose[13]. In contrast, cleavage by endonuclease IV (ref. 13), endonuclease VI (ref. 25) and human placental AP endonuclease[26] is on the opposite side of the base-free deoxyribose residues so as to yield nicks containing 5′-terminal deoxyribose-5-phosphate. Thus, the AP endonucleases associated with DNA glycosylase activities are all of the same type and are distinct from those of the AP endonucleases lacking apparent associated DNA glycosylase activity (at least for the limited number characterized to date). It is also possible that the AP endonuclease components of endonuclease III and T4 UV endonuclease are derived from a common source. However, the detergent Triton X-100 stimulates both the AP and UV endonuclease activities of endonuclease III some 5- to 10-fold, but it is without effect on either the AP- or UV-specific endonucleolytic activity present in our preparation of T4 UV endonuclease. In addition, T4 UV endonuclease fails to cleave OsO_4-treated PM2 DNA[13].

In summary, it is possible that the AP endonuclease activities are not fortuitously associated with their respective *N*-glycosylase components, but instead are companion activities in repair complexes or even single polypeptide chains.

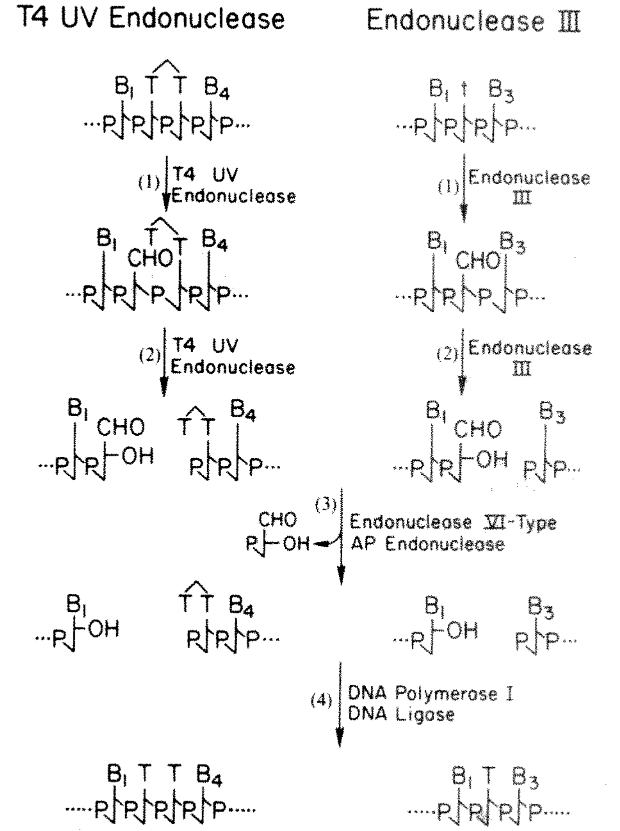

Fig. 3 Excision repair of UV-damaged DNA. The DNA is presumed to be duplex, but for simplicity only one strand is shown. t represents 5,6-hydrated thymine. Endonuclease VI-type refers to AP endonucleases that cleave on the 5′-side of AP sites.

Schemes for UV repair involving DNA glycosylase activities

A scheme for UV repair which extends the base excision studies of Lindahl[6] is emerging from these and related studies[10,13] (Fig. 3). A DNA glycosylase activity specific for pyrimidine dimers (T4 or *M. luteus* UV endonuclease) or 5,6-hydrated thymine (endonuclease III) would first hydrolyse the glycosylic bond of the damaged base. For 5,6-hydrated thymine, the base is completely released from the DNA, as is the case with glycosylase removal of uracil[6], 3-alkyl-adenine[8], hypoxanthine[2] and formamidopyrimidine[9]. For pyrimidine dimers, a structure is formed which retains the dimer in the DNA. It is this pyrimidine dimer attached by only a single glycosylic bond which releases a single pyrimidine when exposed to a secondary dose of irradiation. Judging from the results of Minton *et al.*[27], photoreactivating enzyme *in vitro* would also be capable of acting to cleave dimers at these nicked sites.

Following glycosylase action, two routes are possible for endonuclease incision: hydrolysis of the bond either on the 5′- or on the 3′-side of the AP site. Cleavage on the 3′-side, as has been shown for preparations of endonuclease III and T4 UV endonuclease[13], yields a nick containing a 3′-terminal deoxyribose. Such a structure is an ineffective primer for *E. coli* DNA polymerase I (ref. 13), but can be rendered effective by removal of the 3′-terminal AP site. This removal can be carried out by endonuclease IV or endonuclease VI of *E. Coli*[13], resulting in a gap of one nucleotide at the site of damage (Fig. 3). DNA polymerase I can then excise and resynthesize the damaged region, with DNA ligase restoring the continuity of the DNA to complete the repair. Alternatively, initial cleavage at the AP site arising from glycosylase action might be carried out by an AP endonuclease that leaves a 5′-terminal AP deoxyribose and 3′-OH terminus. As shown previously[13], such nicks directly provide efficient primer termini for *E. coli* DNA polymerase I.

It now seems that in *E. coli*, specific excision repair pathways might proceed via base-excision with specificity for the type of damage lying with DNA glycosylases, while strand incision would occur by virtue of AP endonuclease specificity. Alternatively, apurinic sites might be repaired in a single step by insertion of the appropriate purine base[28]. Endonuclease incision at damaged nucleotide residues would then occur as a back-up mechanism and for cases where no specific glycosylase is available. Such repair would be mediated by enzymes such as endonuclease V, or the *uvr*ABC complex, which appear to recognize many abnormalities in DNA[5,29], rather than by the more specific enzymes such as endonuclease III.

We thank Rufus Day for suggesting the photoreversal experiment; P. Brooks and E. Haeusslein for preparing the T4 UV endonuclease; J. B. Neilands and B. N. Ames for allowing use of HPLC equipment; and Paul Howard-Flanders for helpful discussions. This work was supported by NIH grants GM 19020 and ES 07075 and contract DE-AS03-76-SF34 from the U.S. Department of Energy.

Radio jets and bridges in the classical double sources 3C388 and 0816+526

Jack O. Burns*

National Radio Astronomy Observatory, VLA Program, Socorro, New Mexico 87801

Wayne A. Christiansen

Department of Physics and Astronomy, University of North Carolina, Chapel Hill, North Carolina 27514

We report on 4885-MHz full synthesis high-resolution (1″) observations [using the NRAO Very Large Array (VLA)] of the 'classical' double radio sources 0816+526 and 3C388. Classical double sources are characterized by strong emission peaks (lobes) at the extremities of a linear structure. Although at lower resolution these sources both appear to have simple double-lobed morphologies, the VLA maps reveal several important new features. 0816+516 was found to have very sharp leading edges indicative of strong deceleration, possibly as a result of encountering a dense extragalactic background gas. The transverse boundaries of the components are also quite steep but still consistent with constant emissivity-filled cylinders rather than limb-brightening. The morphology of 3C388 is dramatically different from 0816+526, since it includes a bright radio jet. Unlike previously observed radio jets which are usually found between the nucleus of the radio galaxy and its extended lobes, the jet in 3C388 is embedded inside the southwestern lobe and a prominent gap in the radio emission exists between the radio nucleus and the beginning of the jet. These observations clearly illustrate that a variety of source substructures, which must be dealt with in theoretical models, exist within radio galaxies which were previously classified simply as classical doubles.

0816+526 and 3C388 were chosen for detailed study with the VLA because their morphologies as seen in lower-resolution maps are typical of classical doubles. 0816+526 is associated with a galaxy in the direction of the cluster Abell 643 (distance class 5), although there is no redshift information to confirm its membership[1]. 3C388 (ref. 2) is identified with a cD galaxy ($z=0.0917$)[3] in the direction of a poor cluster. Both sources are quite luminous with 178-MHz radio powers, P_{178}, of $\gtrsim 3\times 10^{25}\,\mathrm{W\,Hz^{-1}\,sr^{-1}}$ for 0816+526 (assuming $z\sim 0.14$) and 3C388. Furthermore, both radio galaxies meet Fanaroff and Riley's Class II criteria (that is, most of the radio power emanates from the source extremities)[4]. The VLA maps of these radio galaxies have revealed a variety of structures which are as rich and complex as those seen in the lower luminosity doubles[5,6]. Several of these newly discovered features raise some interesting theoretical questions.

3C388 and 0816+526 were observed during a 24-h period on 9–10 July 1979 with the VLA. For these observations, a total of 16 antennas were available in the array with baselines ranging from ~60 m to ~18 km. Although the spacings were distributed non-uniformly (grouped heavily with baselines ≤2 km), the resulting *u*, *v* coverage allowed us to adequately map structures at most position angles in these high-declination sources. A bandwidth of 50 MHz centered on the frequency 4885 MHz ($\lambda=6$ cm) was used. The data were collected, edited and calibrated in a fashion similar to that discussed in Owen *et al.*[7]. 'Dirty' maps were constructed and 'cleaned' using the standard techniques.

Contour maps of the total intensity distribution for 0816+526 and 3C388 are shown in Figs 1 and 2, respectively. The shaded ellipses illustrate the FWHM contour of the elliptical clean beams used in restoring the maps.

The crosses in Figs 1 and 2 mark the positions of optical objects in the fields as seen on the Palomar Sky Surver (PSS) E-prints. The sizes of the crosses represent the formal 1″–2″ error in the optical measurements but they do not reflect the error in locating the galaxy nucleus on the overexposed images of the PSS. It is this second error which is likely to be responsible for the offset of the cross in Fig. 2 from the presumed 'nuclear' radio component in 3C388.

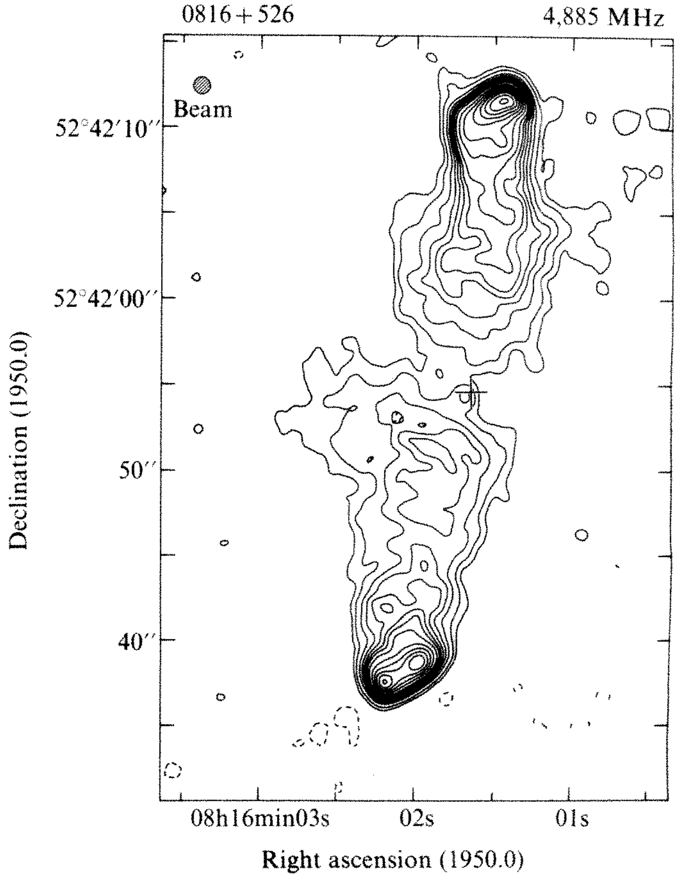

Fig. 1 Total intensity contour map of 0816+526 at 4,885 MHz. The contour levels are 21, 19, 17, 15, 12.6, 10.5, 8.4, 6.3, 5, 4.2, 3.6, 2.5, 1.7, 0.84, 0.42, −0.42, and −0.84 mJy per clean beam area. The shaded circle represents the half-power contour of the VLA clean beam (1″). The cross marks the position of the galaxy identified with 0816+526 as measured from the PSS E-print for this field.

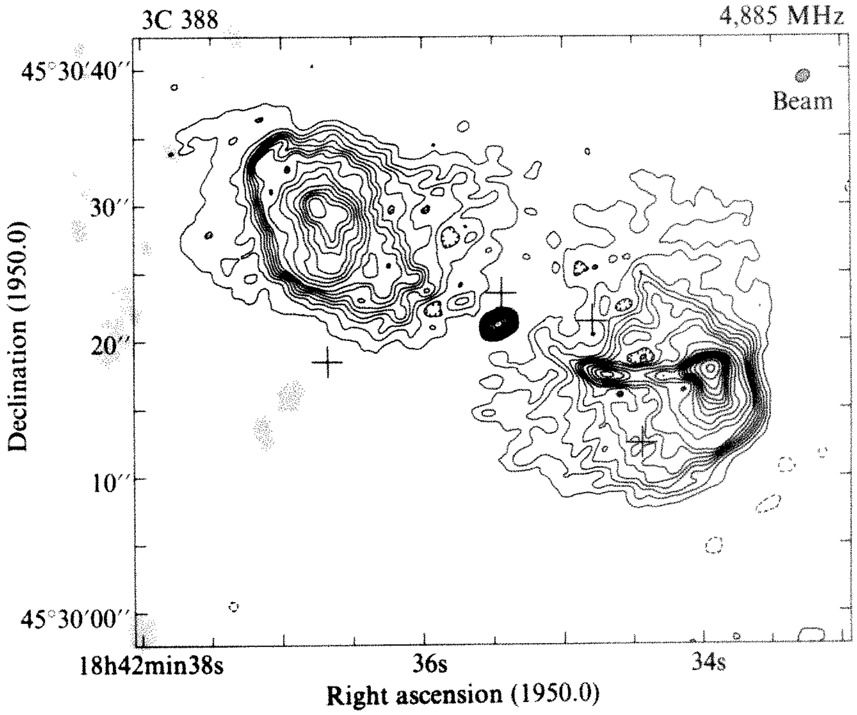

Fig. 2 Total intensity contour map of 3C388 at 4,885 MHz. The contour levels are 62, 50, 37, 25, 19, 13.6, 12.4, 11, 10, 8.7, 7.4, 6.2, 5, 4.3, 3.7, 3.1, 2.5, 1.9, 1.2, 0.6, −0.6, and −1.2 mJy per beam. The peak on this map is 62 mJy. The shaded ellipse represents the half-power contour of the VLA clean beam (1.2" × 0.9", p.a. = −61°). The crosses mark the positions of galaxies in the field of this source as measured from the PSS E-print.

The rich variety seen in the fine structures of both of these sources, in conjunction with high resolution observations of other double sources[6,8-10] indicates that the simple 'classical' double structure previously observed in many radio sources may often be an artifact of insufficient resolution. The new features, such as jets, shells and hot spots which are revealed, may provide the impetus for the testing and development of more detailed theories of radio source evolution. In what follows, since the structures of these two sources are qualitatively different, we shall discuss the structure of each source separately.

Referring to Fig. 1, this source has very sharp leading edges on both the northern and southern extremities. Both of these leading edges are curiously flattened (dense concentration of flux contours) along nearly parallel lines (to within 5°) at position angles of about 57° possibly indicating a large-scale symmetry in the source confinenent mechanism.

The northern component of 0816+526 contains a very intense hot spot ($S_6 = 21.2$ mJy per clean beam area) elongated in p.a. 55°, while the southern component contains a pair of hot spots ($S_6 = 17.2$ mJy per beam and $S_6 = 16.8$ mJy per beam) having nearly equal intensities whose axis lies at p.a. 60°. The strong concentration of the flux contours of both components toward the leading edges implies that steep gradients exist in the internal pressures in both components. This might be expected, if both components are strongly decelerated, possibly as a result of encountering an enhanced background density located well outside the parent galaxy. This dense background gas might be attributed to gaseous remnants from previous activity. An encounter with an enhanced density is also consistent with the sudden reductions in the transverse dimensions of each component observed at declinations of $\delta = 52°41'50"$ and $\delta = 52°42'06"$, respectively. Numerical calculations[11] show that these factors of 2 reductions in transverse radii (as measured from second moments of the one-dimensional strip scans)[12] can be induced by encounters with backgroung media whose densities are enhanced by about a factor of 10.

Another feature of 0816+526 which differs from the structures usually observed in extended doubles is the existence of sharp boundaries along the trailing sides of both components. This is especially noticeable along the sides of the northern component. We have investigated the possibility that trailing regions of this source might be 'limb-brightened' (in the sense that the volume emissivity near the outer boundary of the source exceeds the axial emissivity) by comparing brightness distributions along transverse cuts at declinations between $\delta = 52°41'44"$ and $\delta = 52°42'10"$ with the brightness distributions expected from constant emissivity-filled cylinders whose axes are perpendicular to the line of sight. We find no evidence for limb-brightening since none of these cuts have brightness distributions which rise significantly faster than the constant emissivity case. Even the region in the north component with sharp sides ($52°42'06" < \delta < 52°42'10"$), the brightness distribution can be adequately described by two parameter (radius, peak brightness) least squares fits with filled cylinders ($0.92 <$ correlation coefficient < 0.95; probability that correlation could result from random data in $<0.1\%$). As pointed out by De Young[13], limb-brightening is likely to occur in theoretical models of ram pressure radio sources (whether beams, plasmoids or massive objects) in which relativistic particles are transported and/or accelerated in the sources bow shock. Our failure to detect limb-brightening in this source which has such well-developed hot spots and sharp leading edges seems to indicate that bow shock transport is not likely to be the dominant mechanism for injecting relativistic particles into the trailing regions.

Although the luminosity of 3C388 is roughly comparable to the estimated value for 0816+526, the morphology of this double source is dramatically different as shown by the total intensity map (Fig. 2). Certainly the most interesting feature in this source is the complex jet which is embedded in the south-western lobe. The inclusion of this jet in an extended lobe is remarkable since all radio jets observed previously[5-7] have been located between the galactic nucleus and any extended radio lobes which might be present. In 3C388, however, there is a very noticeable gap in the radio emission between the galactic nucleus and the jet. Furthermore, the jet, which runs almost directly east–west, is definitely not parallel to the double source major axis, having an inclination angle of about 30° with respect to this axis.

The jet (average $S_6 \sim 8$ mJy per beam, percentage polarization, $\pi \leqslant 5\%$) contains two prominent hot spots at opposite extremities (western hot spot: $S_6 = 41.1$ mJy per beam and $\pi \sim 20\%$ polarized, eastern hot spot: $S_6 = 11.2$ mJy per beam and $\pi < 5\%$). The high-intensity contours of the very bright western hot spot are extended toward the south, a direction which is nearly perpendicular to both the jet and the source major axis. Also, extensions in the low-level contours of the eastern hot spot appear to point towards a very intense nuclear radio component ($S_6 = 62$ mJy per beam) located at the centre of the optical galaxy.

The structure of the northeastern lobe of 3C388 contains two interesting substructures. First, this lobe has a sharp 'V'-shaped ridge embedded in an amorphous region of low-level radio emission. (Apex of the 'V' is $\alpha = 18$ h 42 min 37.5, $\delta = 45°30'34''$.) The ridge is highly polarized ($\pi \sim 25$–30%) with a possibly circumferential magnetic field configuration. This polarization structure will be discussed in more detail elsewhere. Second, the rather diffuse hot spot in this component is located well back from the leading edge of the lobe. Both the jet and the 'V'-shaped shell are missing in the 8-GHz map of De Young *et al.*[14], thus raising the possibility that these regions of the source may have steep spectra ($\alpha > 0.8$ where $S_{\nu}\alpha^{-\alpha}$).

Neither of these sources has a structure which appears to be compatible with either of the extremes in the spectrum of ram pressure confined radio source models: namely, simple continuous beam models on the one hand and single injection plasmoid models on the other. Rather, what seems to be called for is some sort of intermittent beam or multiple explosion model; two concepts in which distinctions have become somewhat blurred. A major remaining distinction between these theoretical models does exist in terms of the plasma density assumed to exist inside the observed radio lobes, with the beam models generally invoking a low-density plasma while the plasmoid models invoke high densities.

As mentioned previously, an attractive interpretation for the structure of 0816+526 invokes the penetration of the radio source into an enhanced background density. The intense hot spots in both components of 0816+526 are then attributable to Rayleigh–Taylor instabilities driven by the large deceleration associated with the enhanced background density. In fact, the rapid growth of Rayleigh–Taylor instabilities, along with a general contraction induced by encountering a higher density, may trigger the type of radiative instabilities discussed by Eilek and Caroff[15] and Christiansen *et al.*[16].

For 3C388, physical conditions seem to be quite different. It seems that this source may involve an interaction between an intermittent beam and/or a fresh plasmoid and the boundaries of an evacuated cavity or bubble. The obvious differences in appearance of the major lobes can then be ascribed to the possibility that the two lobes are in different stages of development. That is, in the southwestern component the leading edge of the beam has already impacted on the shell of the cavity creating the observed hot spot. The jet might then be interpreted as being a narrow part of the beam which has not yet reached the shell or perhaps as a reflection jet of plasma which has been focused by and rebounded from the external shell. This latter possibility[17] is particularly intriguing because of the jet's well-collimated structure and lack of polarization.

The northeastern lobe of the source is then interpreted as being in a less well-developed stage in which a new radio component (represented by the diffuse hot spot) is just beginning to make contact with the steep-spectrum shell source. As this plasma rams further into the apex of the shell it should be decelerated and develop a higher surface brightness more closely resembling the structure of the southwestern component.

We thank Frazer Owen, Jean Eilek, and Lawrence Rudnick for critical readings of the manuscript, Roger Blandford and Dave De Young for comments on our interpretations of the source structures, and David Hough for help with data reduction. W.A.C. thanks NRAO for a summer faculty fellowship and the Morehead Foundation at the University of North Carolina for financial support.

Short-term variability of Cyg X-1 and the accretion disk temperature fluctuation

Kohsei Doi*

Institute of Space and Aeronautical Science, University of Tokyo,
Komaba, Meguro-ku, Tokyo 153, Japan

Recent thoretical models of Cyg X-1 (refs 1–5) assume that to explain the observed time-averaged spectrum the hard X rays are emitted by inverse-Compton mechanism from an optically thin, hot accretion disk around a black hole. Numerous observations (especially in the energy range$\gtrsim$20 keV) have shown that the source intensity is variable on different time scales[6–17]. Short-term variability on the time scale of ~1 s is especially conspicuous because of its stationary nature and the stability of time scale[6–11]. A balloon observation was carried out to study the variability in the hitherto unknown hard X-ray range ($\gtrsim$20 keV). The results of the analysis, together with those of the former rocket observation, suggest that the variation is essentially spectral, implicating that it originates from temperature fluctuation in an accretion disk. Such a model is discussed here in detail.

Although it has been suggested, along with the shot-noise model, that the variability is caused by local hot spots[9], how such hot spots are generated and decay in an accretion disk with the relevant time scale remains obscure. Moreover, our previous rocket observation (1.5–25 keV) revealed the complete correlation between the variations of different energy bands (that is, the energy independence of the characteristic time scale ~1 s) and energy dependence of the relative amplitude of the variation[11], which presents difficulty to the simple shot-noise model[11,18]. To obtain a wideband picture of the variation, I made a balloon observation in the hard ($\gtrsim$20 keV) X-ray range with a large effective area (~3,000 cm^2) detector comprising pressurized xenon gas proportional counters[19,20]. The balloon flight was carried out on 22 May 1977 in collaboration with the balloon group of ISAS, University of Tokyo.

The coefficient of variation method of analysis[11,19] was applied to the balloon data to compare it with the rocket observation. The coefficient of variation for a data bin-width t_b, $\eta(t_b)$, is defined as the standard deviation of the variation intrinsic to Cyg X-1 normalized to its average intensity; it is a dimensionless measure of the amplitude of variation, and as a function of t_b it carries information on the characteristic time τ($\eta(t_b)$ is constant for $t_b \lesssim \tau$ and decreases monotonously for $t_b \gtrsim \tau$ as the variation is smoothed out).

The results are shown in Fig. 1 for the balloon data in two energy bands (20–35, 35–68 keV) with the previous rocket data in three energy bands. The characteristic time is about the same(~1 s), but there is a striking difference in energy dependence of the amplitude of variation between low (rocket) and high (balloon) energies; for the soft X rays ($\lesssim$25 keV) the lower the energy, the greater the amplitude of variation, while the opposite is true for the hard X rays ($\gtrsim$20 keV).

The relation between the variations observed in different experiments at different times is unknown, so there are

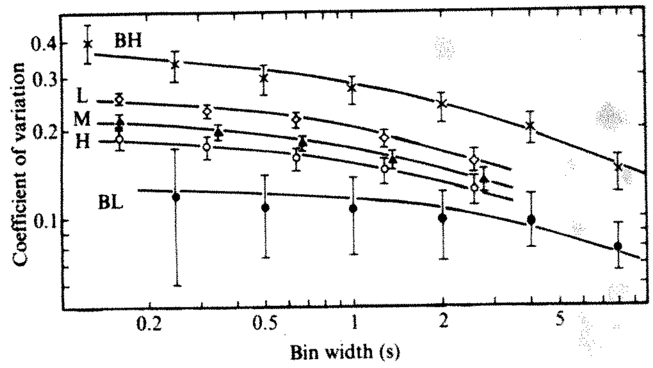

Fig. 1 Coefficients of variation plotted against data bin width for the balloon (BL, 20–35; BH, 35–68 keV) and rocket (L: 1. 5–5; M, 5–10, H; 10–25 keV) data.

difficulties when combining the results to make one picture. The difficulty associated with long-term variation may be alleviated by the average flux data in both experiments being consistent with the normal state spectrum. Assuming that the variation is stationary (which is justified at least in $\lesssim 20$ keV range, because it was observed in virtually all the high time-resolution measurements, deriving essentially the same characteristic time scale ~1 s) there are three possible interpretations: the soft and hard X-ray variations are (1) positively correlated, (2) statistically independent, or (3) anti-correlated. Although none of these can be ruled out by present observational knowledge, note that the third interpretation (which claims that the variation is essentially spectral, keeping the total X-ray luminosity approximately constant although a narrow-band observation indicates intensity variation, see Fig. 2) is consistently accommodated by the accretion disk model. Spectral variation means that the fluctuation of the electron temperature, and a built-in mechanism of such a fluctuation, does exist in the hot disk proposed in the current models.

Energetics in the disk can be summarized as follows. Gravitational energy of accreting matter is absorbed by ions through viscous dissipation and subsequently transfers to electrons through Coulomb collisions. Electrons are cooled by comptonization of low energy (soft) photons, emitting the bulk of energy as hard X rays. The cooling time scale τ_c(~ms) is much shorter than the time scale of Coulomb coupling $\tau_{ei}(\propto n^{-1}T_e^{3/2})$, hence the disk is in the two-temperature state[3,5] ($T_i \gg T_e$; note that $(T_i - T_e)/\tau_{ei} = T_e/\tau_c$ from energy balance). Now if the luminosity of soft photons (L_s) fluctuates, then it will cause the kind of variation suggested from the observations. As the energy supply rate (originally determined by the accretion rate) is considered to be constant ($\sim T_i/\tau_{ei}$) on the time scale of seconds, the energy spectrum has to change to keep the total X-ray luminosity approximately constant. For example, when L_s increases, Compton cooling will lower T_e and a soft (steep) spectrum will result. Stochastic fluctuation of L_s would be expected in the hot disk, which is set up by instabilities and where turbulence is the main source of viscosity.

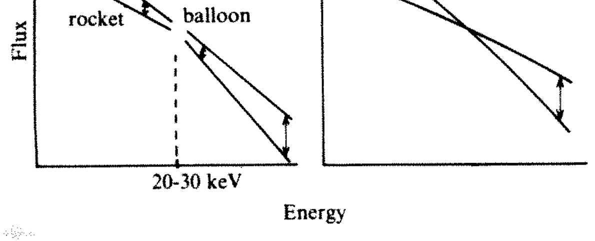

Fig. 2 *a*, Illustration of the energy dependence of the short-term variation derived from the rocket and balloon observation; *b*, a tentative interpretation.

The simplest description of the variation of T_e is

$$\frac{dT_e}{dt} = \frac{T_i - T_e}{\tau_{ei}} - CL_s(t) \tag{1}$$

where the first and second terms in the right hand side represent Coulomb heating and Compton cooling respectively. (The cooling effect is assumed to be proportional to L_s for simplicity; thus $C\langle L_s(t)\rangle = \langle T_e\rangle/\tau_c$ to meet the steady state solution.) Equation (1) is a Langevin equation[18] for stochastic variable $L_s(t)$. Assuming that $L_s(t)$ fluctuates with a time scale τ_s, so that its power spectrum $I_s(\omega)$ is in the form

$$I_s(\omega) \propto \frac{1/\tau_s}{\omega^2 + 1/\tau_s^2} \tag{2}$$

The autocorrelation function of $T_e(t)$ is then,

$$\langle T_e(t)T_e(t+\tau)\rangle \propto \frac{\tau_{ei}\exp(-|\tau|/\tau_{ei}) - \tau_s \exp(-|\tau|/\tau_s)}{(\tau_{ei} - \tau_s)} \tag{3}$$

Note that τ_{ei} is the only long (~1 s) time scale in the inner hot disk, which reflects the high temperature state ($T_i \sim 10^{11}$, $T_e \sim 10^9$ K). τ_s is expected to be much shorter as L_s is considered to originate from cold and dense clumps in the hot disk, where relevant characteristic times (keplerian and hydrodynamic ones) are of the order of milliseconds (ref. 5). Then, equation (3) indicates that the time scale of the variation of T_e (and of X rays) is ~1 s just as observed.

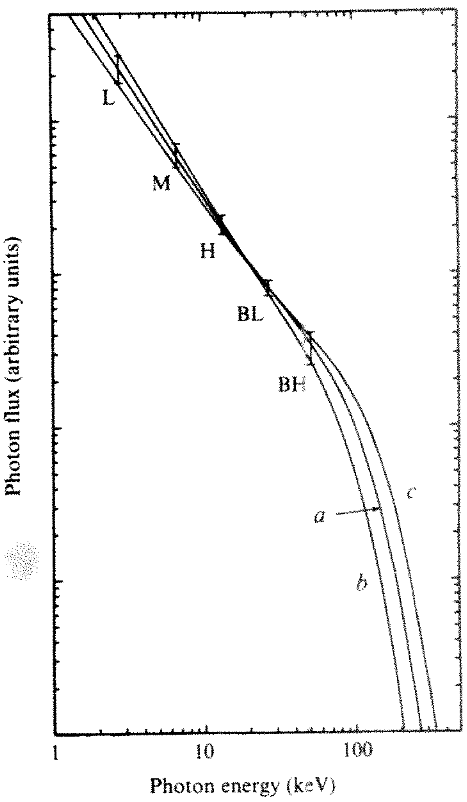

Fig. 3 Theoretical comptonization spectra for *a*, the best-fit parameters $kT_e = 27$ keV and Thomson optical thickness = 5; *b*, $kT_e = 21$ keV; and *c*, $kT_e = 33$ keV, normalized to the total X-ray luminosity (1–300 keV). Vertical bars labelled L, M, H, BL, and BH show ±1 standard deviation of the variations derived from the coefficients of variation at bin-width of 0.5 s (Fig. 1). Each bar is placed at the mean energy of corresponding energy band.

Recently Sunyaev and Trümper[21] have compared the new observational and theoretical results to derive the best-fit disk parameters including a much smaller T_e ($kT_e = 27$ keV) than previously believed. Their theory is based on the (time-averaged) hard X-ray spectrum with high statistical accuracy obtained from balloon observations by the AIT/MPI group and the analytical solution for the comptonization spectrum from a spherical isothermal electron cloud. Their results give more semi-quantitative support to the present model. Figure 3 shows the theoretical spectrum for the best-fit parameters (kT_e = 27 keV, and Thomson optical thickness =5) and the spectra for T_e a little (~20%) higher and lower, normalized to the total X-ray luminosity. The node of the flux variation is indeed at 20–30 keV as suggested from the observation. Figure 3 also shows the ±1 standard deviation of the variations for various energy bands derived from the observational data (Fig. 1) for comparison.

The present model explains the stochastic nature of variability, its characteristic time scale and spectral features at the same time in the context of the conventional accretion disk model for Cyg X-1. Furthermore I suggest that the complex variability of Cyg X-1 over a wide span of time scale may be classified into three categories: (1) non-stationary long-term variation on the time scales from ~10 s (ref. 17) to ~10^6 s (high-low transition[12–15]) due to fluctuations in the outer cool disk and changes in accretion rate[5]; (2) stationary short-term variation discussed here; and (3) millisecond pulsation[16] which presumably reflects the intrinsic time scale to the inner hot disk. A more refined version of extended-range, high time-resolution observation will clarify the nature of the variability.

I thank Professors M. Oda, J. Nishimura, S. Miyamoto and Y.Ogawara for useful discussions.

The 20-μm brightness temperature of the unilluminated side of Saturn's rings

Alan T. Tokunaga*, John Caldwell† & Ira G. Nolt‡

The 20-μm brightness temperature of the unilluminated (north) side of Saturn's rings is reported here to be 56±1 K. This measurement, together with previous measurements of the rings at 20 μm, shows that the brightness temperature of the B ring can be approximated by the simple equation $T_B^4 = 56^4 + 1.52 \times 10^8 \sin|B'|$, where B' is the saturnicentric declination of the Sun. We have assumed that emission from the Cassini division is negligible. The constants in this equation may be understood in terms of a two-component heating model for the ring particles—sunlight and radiation from Saturn. We discuss the implications of the IR data for several published ring models.

Table 1 19.8 μm photometry

Ring position flux	$5.75 \pm 0.22 \times 10^{-19}$ W cm^{-2} μm^{-1}
Sky position flux	$3.57 \pm 0.18 \times 10^{-19}$ W cm^{-2} μm^{-1}
Net ring flux	$2.18 \pm 0.40 \times 10^{-19}$ W cm^{-2} μm^{-1}
Ring brightness	$5.88 \pm 1.08 \times 10^{-9}$ W cm^{-2} μm^{-1} sr^{-1}
Corrected ring brightness*	$9.06 \pm 1.66 \times 10^{-9}$ W cm^{-2} μm^{-1} sr^{-1}
Ring brightness temperature	56.0 ± 0.9 K

*See text.

Previous observations showed that the brightness temperature of Saturn's B ring gradually decreased as B' diminished. The current time period is critical because observations at the small values of B' can most effectively distinguish between competing models for the B ring, as shown by Nolt *et al.*[1]. In addition, for several months near the beginning of 1980 the unilluminated side of the rings could be observed from the Earth. This opportunity arises whenever the Earth and the Sun are at opposite sides of the plane of the rings, as can occur during the ring plane crossing[2]. The first IR observations of the unilluminated side of the rings were made with the Pioneer 11 spacecraft, which found a 45-μm brightness temperature of ~55 K (ref. 3). [Ingersoll (personal communication) now considers the Pioneer 11 observation of the unilluminated side of the rings to be a firm detection rather than an upper limit.]

The observations were made with the 3-m IR Telescope Facility (IRTF) at Mauna Kea on Hawaii on 6 January 1980 (UT). A newly developed 2–30-μm liquid helium cooled bolometer system was used for the observations. For the ring observations, a 2-arc s aperture was used with a cooled 19.8-μm filter (Δλ = 6 μm) which defined the wavelength interval. The aperture was centred on the B ring ansa, but the small opening of the rings (the maximum extent of the minor axis was 1.7 arc s) prevented the separation of the A and B rings. The C ring was completely out of our aperture.

The centre of the B ring ansa was only 6 arc s from the edge of the disk of Saturn, and as a result scattered and diffracted radiation from the disk produced a spurious signal (which we call 'sky' signal). We have measured the sky signal at the same radial distance from the limb as the rings but displaced 4 arc s north and south. The signal at the ring position and the adjacent sky is shown in Table 1 (the north and south sky measurements have been combined). As there was no significant difference in the signals at the ring position between the A and B ring ansae, the signals at both ansae have also been combined in Table 1.

The difference in measured flux between the ring and sky positions was $2.18 \pm 0.40 \times 10^{-19}$ W cm^{-2} μm^{-1}. The quoted error is the sum of the errors of the ring and sky positions and is therefore a conservative estimate. The solid angle of the rings within our aperture was determined graphically to be 3.71×10^{-11} sr, using previously published constants[4], so that the surface brightness of the rings is $5.88 \pm 1.08 \times 10^{-9}$ W cm^{-2} μm^{-1} sr^{-1}.

The first dark ring of the Airy diffraction pattern of the telescope has a diameter of 3.4 arc s. Therefore, some of the flux from the ring was diffracted out of the beam. From a two-dimensional convolution of the diffracted ring with our aperture, we estimate that approximately 35±5% of the ring flux was diffracted out of the beam. After adjusting for this we obtain a corrected ring brightness of $9.1 \pm 1.7 \times 10^{-9}$ W cm^{-2} μm^{-1} sr^{-1}, which corresponds to a brightness temperature of 56±1 K at 19.8 μm. This brightness temperature agrees very well with that measured by Pioneer 11 at 45 μm.

It is difficult to correct our result for the emission from the Cassini division because its optical depth and brightness temperature are both very uncertain. The normal optical depth has recently been estimated to be in the range 0.01–0.05 (refs 5–7). For this range of optical depth, the brightness temperature of the Cassini division must be less than 64–71 K for the Cassini division to emit less than 10% of the observed emission. As Nolt *et al.*[1] found that the C ring brightness temperature was 82–85 K at $B' = -6.5°$, a brightness temperature for the Cassini division

†Range of 45-μm brightness temperature from Pioneer 11.

of ≤ 70 K at the time of our observations ($B' = -0.881°$) is plausible. In the following we assume that the emission of the Cassini division is neglible, pending more precise estimates of the optical depth and brightness temperature of the Cassini division.

The ring brightness temperature must be very close to the actual temperature of the unilluminated side of the rings, as the rings are opaque in the line of sight. From the B ring normal optical depth of ≈ 1 at visual wavelengths[8], we estimate the visual line of sight transmission in the direction of the Earth to be $1/\exp(1/\sin 1.72°) \approx 10^{-15}$, where 1.72° is the saturnicentric declination of the Earth. Therefore, with unit emissivity, the physical and brightness temperatures would be identical. For all plausible emissivities, the difference will be very small. For example, at 20 μm, an emissivity of 0.8 would result in an underestimate of the physical temperature of less than 1 K.

We further suggest that our result for the dark side provides a measure of the A and B ring brightness temperature in the absence of solar heating, the condition achieved when $B' = 0°$. Direct solar heating certainly does not influence our observation, as the line of sight transmission for sunlight is even less than the transmission as viewed from the Earth. Heating of the dark side by scattered sunlight is possible[9], but we ignore it for the present. A qualitative explanation of the observed ring brightness of the unilluminated side as discussed below does not require additional heating by scattering.

Our measurement is shown in Fig. 1 along with previous 20-μm observations of the B ring that are listed in Table 2. No correction for the distance of Saturn from the Sun has been applied. Such a correction, as applied by Nolt *et al.*[10], results in a change of brightness temperature of ≤ 1 K, which is less than the uncertainty in the measurements. A very good fit to the data can be obtained using the empirical formula

$$T_B^4 = T_0^4 + C \sin |B'| \qquad (1)$$

where T_0 and C are constants. The first term on the right accounts for the heating from the disk of Saturn that results from reflected solar radiation and IR emission from Saturn. The second term in equation (1) accounts for solar heating as a function of B', a parameterization which has been suggested previously by Murphy[11] and by Pollack *et al.*[12] for various simplified ring models.

Our observations give $T_0 = 56$ K because this is the expected value of the B ring temperature for $B' = 0$ as discussed above. We have neglected here any difference in the A and B ring temperature, because we do not have sufficient information for a two-parameter fit. We find that a value of $C = 1.52 \pm 0.17 \times 10^8$ K^4 gives the best fit to the data, as shown in Fig. 1.

Can the ring temperature of 56 K be explained only from heating by the disk of Saturn? We assume that an idealized ring particle is illuminated by Saturn on only half of its northern hemisphere. Radiation from Saturn from the other side of the ring plane is assumed to be blocked by other ring particles. We then obtain the following simple radiation balance equation

$$(1 - A)f = 4\,\alpha e \sigma T_0^4 \qquad (2)$$

where A is the Bond albedo, f is incident flux from Saturn (W m^{-2}), e is the particle emissivity, σ the Stefan–Boltzmann constant and T_0 the physical temperature of the ring particle. α is a constant which is 1 if the particle radiates into 2π sr and 2 if the particle radiates into 4π sr. The Bond albedo is very uncertain, but a value of 0.6 seems reasonable[13].

For $A = 0.6$ and $T_0 = 56$ K, we obtain from equation (2) the following expression for the incident flux from Saturn

$$f = 5.58\,\alpha e \text{ W m}^{-2} \qquad (3)$$

This can be compared with the expected incident flux at the centre of the B ring resulting from the reflected solar radiation from the disk of Saturn and the IR radiation of Saturn. Assuming an effective temperature of 94.4 K (ref. 3), we find that the incident flux at the centre of the B ring to be 1.4 W m^{-2}. In addition, for an albedo of Saturn's disk of 0.45 (refs 3, 14), we find that the reflected solar radiation (into 2π sr) contributes an additional 1.1 W m^{-2}. The total amount of incident flux is therefore 2.5 W m^{-2}. This is in good agreement with equation (3) if $\alpha e \approx 0.5$. Both α and e are unknown, but for $e = 0.5 \rightarrow 1.0$—a possible range of emissivity—the particle may radiate into $\approx \pi \rightarrow 2\pi$ sr ($\alpha \approx 0.5 \rightarrow 1$) in this simple model. We conclude that the measured brightness temperature of 56 K can be understood qualitatively in the context of single particle radiation balance. The more realistic multi-particle, multilayer model is discussed below.

The second term in equation (1) can also be understood in terms of a simple model. Following Pollack *et al.*[12], the radiation balance of the rings with sunlight is

$$(131.8\text{ K})^4 \sin |B'|(1 - A - T_r) = \alpha e T^4 \qquad (4)$$

where T_r is the transmissivity of the rings and T is the ring physical temperature due to solar heating. B', A, e and α have the same definitions as before. The constant 131.8 K is the temperature of a black disk in equilibrium with the solar radiation at Saturn's distance from the Sun. As discussed above, the transmissivity of the rings is negligible for small B'. Assuming $A = 0.6$ and $T_r = 0$, we obtain from equation (4)

$$T = \frac{1.21 \times 10^8}{\alpha e} \sin |B'| \qquad \text{K}^4 \qquad (5)$$

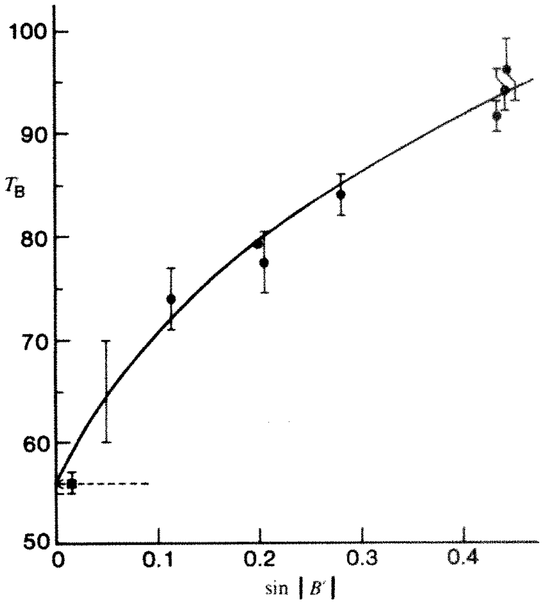

Fig. 1 B ring brightness temperature at 20 μm as a function of sin B'. The solid curve shows the fit achieved with the expression $T_B^4 = 56^4 + 1.52 \times 10^8 \sin |B'|$. The dashed arrow indicates that our measurement of the unilluminated side at $\sin |B'| = 0.015$ is assumed to represent the ring brightness temperature for $B' = 0$, as discussed in the text. All other points are taken from Table 2 and refer to observations of the side of the rings which is illuminated directly by the Sun.

Comparing this expression with the second term in equation (1) with the best-fitting value for the constant C, we see that a reasonable agreement is achieved if $\alpha e \approx 0.8$. Note that the fit is not strictly valid for $B' = 26°$ where $T_r \approx 0.1$.

It is encouraging that roughly the same value for the product αe is obtained in two cases. This increases the possibility that the various parameters have been estimated reasonably well above. However, there are so many areas of uncertainty that we cannot preclude the possibility of fortuitous cancellation for more than one inaccuracy.

The most sophisticated ring model with a prediction for the thermal emission is that by Kawata and Irvine[15]. As shown by Nolt *et al.*[1], this model systematically predicts higher brightness temperatures than observed for $\sin|B'| \sim 0.2$. In addition, this model predicts that $T_0 \sim 50$ K, lower than our observed value. Nolt *et al.*[1] also present the predicted brightness temperature for a two-component model of the rings which fitted the data for $\sin|B'| > 0.1$. This model also fails because it predicted T_0 to be ~ 69 K.

In conclusion, the ring IR brightness temperature on the unilluminated side of the rings has been found to be 56 ± 1 K. The decrease of the B ring brightness temperature is apparently proportional to $\sin|B'|$. These characteristics are not explained by any published detailed ring model, but it can be understood on the basis of single particle radiation balance considerations. These results need to be re-examined if the optical depth and brightness temperature of the Cassini division are found to be outside the limits assumed here.

We thank the staff of the IR Telescope Facility for maintaining the telescope, C. Telesco for providing technical support with the bolometer, and J. Cuzzi for pointing out the possible importance of the Cassini division. J.C. acknowledges the support of NASA contract NSG 7320 during this work. A.T.T. is a Staff Astronomer at the IRTF Facility which is operated by the University of Hawaii under contract from the National Aeronautics and Space Administration. J.C. was a Visiting Astronomer at the IRTF.

Pleistocene bimodal response of Antarctic ice

David J. Drewry

Scott Polar Research Institute, University of Cambridge,
Lensfield Road, Cambridge CB2 1ER, UK

Extent and volume of the Antarctic ice sheet have important roles in modulating global atmospheric and oceanographic processes and have significant implications for world sea levels[1]. The history of ice sheet variations in Antarctica has mainly been founded on studies in the ice free (Dry) valleys of southern Victoria Land (Fig. 1). A detailed glacial chronology by Denton and co-workers[2–4] is based on the premise that Taylor Glacier and neighbouring Wright Upper Glacier are outlets of the East Antarctic ice sheet and that, "the extent of Taylor Glacier reflects the height of this ice sheet, and, since it terminates on land, records of its former positions provide one of the few indications of former heights of the ice sheet"[5]. That the East Anarctic ice sheet reached its maximum dimensions during each of the last four world-wide interglacials is an important conclusion of this work[2]. New geophysical data from Taylor Glacier and the adjacent ice sheet in Victoria Land, Antarctica are presented here which challenge these suppositions.

Between 1967 and 1978 six seasons of airborne geophysical sounding have completed an extensive network of flight lines over East Antarctica[6–8]. Ice thickness profiling has enabled compilation of detailed contour maps of the ice sheet surface to an accuracy[9–11] of ±30 m. Flow lines orthogonal to the contours[12] have been constructed (Fig. 2). In 1974–75 a closely spaced series of Radio Echo Sounding (RES) flight lines was completed over the ice sheet inland of the Dry Valleys (Fig. 3)[13]. These two surveys have defined the pattern of ice flow out of central East Antarctica through the Transantarctic Mountains into the Ross Sea embayment.

In the sector inland of Victoria Land the ice sheet exhibits a wide and prominent ridge which drives ice into the clearly marked catchments of David and Mulock-Byrd Glaciers (Fig. 2). Within 100 km of the western edge of the Transantarctic Mountains, just inland of Taylor Glacier, the ridge terminates in a small dome. The ice sheet drops by more than 100 m into a saddle between this dome and the main part of the ridge. Altitudes determined by barometry along a single traverse line ~30 km south of the dome by Crary during the IGY intimated at a similar elevation distribution[14]. Calkin[15], using less reliable radar results, also suggested the possibility of a dome in this vicinity.

RES surface contours establish a flow pattern in which the now well-defined dome and ridge system effectively blocks ice

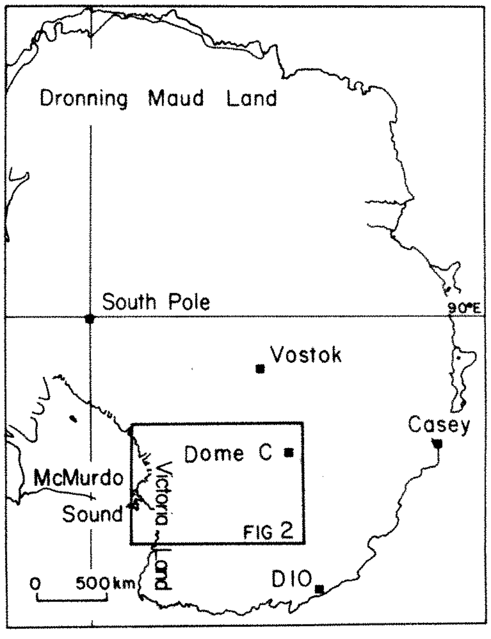

Fig. 1 Antarctic location map (principal places mentioned in text and Fig. 2).

0028-0836/80/380214—03$01.00

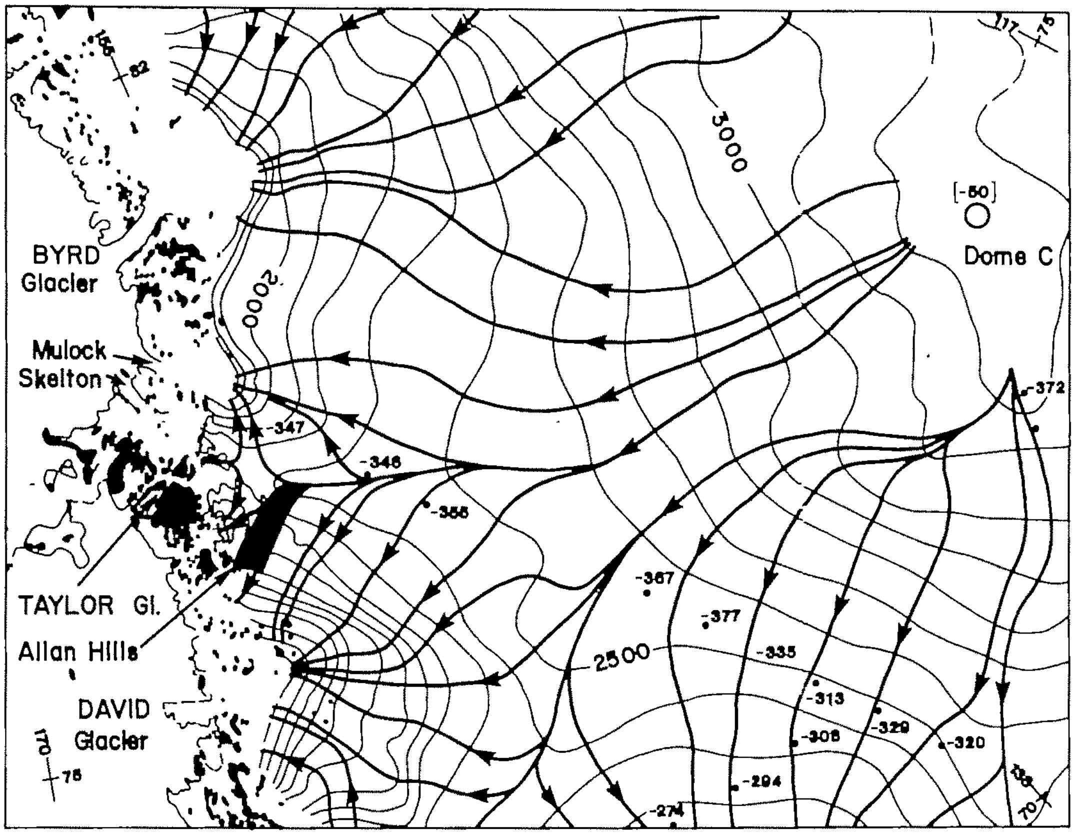

Fig. 2 Ice surface contours and derived flow lines for part of the East Antarctic ice sheet, based on radio echo sounding data[10,11]. Note diverging ice flow from dome inland of Taylor Glacier. Catchment area of ice flowing towards Allan Hills meteorite site is shown shaded. Selected δ^2H and ^{18}O values for surface accumulation are shown[31–33,38].

penetration into the Dry Valleys from central regions of East Antarctica. The catchments, therefore, of small outlet glaciers in southern Victoria Land (for example, Ferrar, Wright Upper, Victoria Upper, Mackay and possibly Skelton) are severely restricted and that of Taylor Glacier is less than 5,000 km^2.

RES results suggest only a local origin for ice in Taylor and adjacent glaciers. To test this hypothesis ice provenance studies, using stable isotope techniques, were performed in January 1978 and January 1979[16].

Five horizontal 1-m ice core samples were taken from the lowermost 1.5 m of exposed ice at the snout of Taylor Glacier in 1978 (Fig. 3). The following season an ice core, 4 m long, was extracted close to the summit of the dome inland of the glacier (Fig. 3). The average accumulation rate in this area is 140 kg m^{-2}yr^{-1} and average snow density in the upper 4 m is 437 kg m^{-3} (refs 14, 17). The core thus sampled 12 yr precipitation and the resulting mean isotopic values are considered representative of surface accumulation at Taylor dome.

Stable isotope results are given in Table 1. Values of δ^2H at Taylor Glacier snout range between −327‰ and −341‰ (the lowermost sample), bracketing similar determinations by other workers[18]. At Taylor dome (the ice divide) δ^2H measurements lie between −341 and −344‰. They correspond closely with those to be expected theoretically[19] given mean annual surface temperature (−43 °C) and elevation (2,400 m). Table 1 also lists isotopic values for ice accumulating in the central parts of East Antarctica. The ice here has a significantly lighter isotopic signature than from southern Victoria Land.

The equivalence of δ^2H ratios at Taylor Glacier snout and at the dome (the difference between the two sets of measurements (3‰) is negligible) strongly suggests that the glacier has been in near isotopic equilibrium for the lifetime of oldest ice sampled, and that the preceding conclusions are valid for several thousand years. Integration with respect to time of maximum surface velocities measured by New Zealand workers[20] gives an estimated minimum period of ice throughput from dome to snout of 10.5 kyr. Corrections applied to particle paths through Taylor Glacier for zones of basal sliding[20] and reduction of velocity with depth[21] give a more realistic throughput time of 15–16 kyr. If these dates are approximately correct we attribute the absence of more isotopically negative ice at the base of Taylor Glacier snout (representing the end of Wisconsin cooling) principally to basal melting upstream. Although ice transit calculations are based on the steady-state assumption they, nevertheless, corroborate glacial geological[3] and geochemical[5,22] conclusions that Taylor Glacier did not expand appreciably during the Wisconsin maximum, and provide no evidence for intrusion of 'cold' East Antarctic ice. Post-Wisconsin advance reported by Denton is attributed to increased local precipitation.

The discovery of meteorites[23] on bare ice at the edge of the Transantarctic Mountains at Allan Hills (100 km north of Taylor Glacier dome) also corroborates the notion of ice sheet stability in southern Victoria Land (Fig. 2). The meteorites have ages between 30 and 800 kyr[24,39] and have been concentrated at

this locality by flow from the surrounding ice sheet and surface ablation[25]. As Allan Hills presents only a low topographical barrier to the ice sheet any significant thickening in this area (>100 m) would effectively flush-out the meteorites into Mawson Glacier. Assuming that the meteorite infall rate in polar areas is $\sim 1\times10^{-6}$ km^{-2} yr^{-1} (refs 26, 27, 40) we calculate for that part of the ice sheet draining towards Allan Hills ($\sim$1,500–3,000 km^{-2}, Fig. 2) the time to accumulate the $\sim$50 'parent' meteorite new finds[23] is 17–33 kyr. We conclude that the ice sheet in the vicinity of Allan Hills cannot have thickened substantially during this period.

The pattern of fluctuations exhibited by local ice in Victoria Land during the last and possibly earlier glacials is out-of-phase with the bulk of the East Antarctic ice sheet where seaward expansion of continental ice during full glacial periods has been established[28–33]. We explain antiphase behaviour as a result of differing glacio-climatic controls. On the high plateau accumulation is relatively low (50–100 kg m^{-2} yr^{-1})[17] due to steady inland water-vapour depletion of precipitation-bearing air masses that penetrate the continent[34]. In contrast snow-fall reaching Taylor Glacier and neighbouring ice masses comes primarily from air advected over the Ross Sea, regulated by seasonal ice cover, degree of open water, cyclogenesis and orographic effects[35,36].

I suggest that during glacial episodes Northern Hemisphere ice build-up results in a major depression of global sea level causing a modest expansion and thickening of the 'stable' East Antarctic ice sheet. Ice in West Antarctica, however, grounded below sea level, expands dramatically across the Ross Sea continental shelf[28,37]: the zone of seasonal pack ice and open water is moved northwards by several hundred kilometres, reducing precipitation to those glaciers with limited catchments. Stability or even recession of the ice sheet margin in Victoria Land ensues.

During Northern Hemisphere interglacials rising sea level will trigger inland retreat of the ice sheet. With incursion of open water into the Ross Sea embayment, however, enhanced water vapour flux over Victoria Land results in modest expansion of the ice sheet edge and associated minor glaciers.

Widespread use of the detailed glacial chronology of the Dry Valleys area requires caution. The relationship of local 'outlet' glaciers to the glaciological regime of the East Antarctic ice sheet is clearly complex and often independent. Such conclusions may apply to similar locations along the inland edge of the Transantarctic Mountains (for example, Queen Maud Mountains and Reedy Glacier areas). Sites for future investigation of continental glacial fluctuations in the Transantarctic and other mountainous areas will require careful assessment and interpretation. The most suitable may be the margins of the premier outlet glaciers whose catchments lie deep within the ice sheet (for example, David, Byrd, Jutalstraumen, Shirase, Lambert and Minnesota Glaciers).

This work was supported by the NERC under grant GR3/2291 and the NSF Division of Polar Programs. I thank C. Lorius for arranging isotopic determinations, and A. Bath (NERC) for similar analyses in the UK, and my colleagues at the Scott Polar Research Institute for fieldwork assistance.

Sublithospheric upwelling distribution

Dork Sahagian

Department of Geological Sciences, Rutgers University,
New Brunswick, New Jersey 08903

Hot spots have been defined[1] as centres of volcanism not associated with plate boundaries. Some authors[2,3] have regarded them as surface expressions of upwellings of relatively high temperature material in the mantle. These upwellings, either deep mantle plumes[2,4], or shallow convection cells[5], create a hot spot on the surface of the Earth only where they have molten and broken their way to the surface. I suggest here that there is a uniform sublithospheric upwelling distribution, and that the ability of upwellings to make themselves evident on the surface, and, therefore, the difference in surface hot spot density among the various plates, depends on the velocity and thickness of each lithospheric plate. From these characteristics and the rate of magma entry into the lithosphere, a normalization of the areal hot spot density can be made to calculate the distance between sublithospheric upwellings.

The major effect of the motion of a plate over a mantle upwelling is to limit the time available for the transfer of heat through the lithosphere. Although the process of lithospheric thinning operates on moving plates[6,7], only a fraction of the sublithospheric upwellings are able to penetrate to the surface.

Lithospheric thickness determines the amount of time necessary for an upwelling to penetrate the lithosphere. The thickness depends primarily on the dynamic history of the plate involved, and in particular, its age, which for oceanic regions is related to the distance from the spreading centre[8,17].

The rate of intrusion is important in thinning the lithosphere. This determines the rate of ascent of the lithosphere–aesthenosphere boundary.

The sublithospheric upwelling density (expressed as area per upwelling) can be calculated from the above parameters for each plate using the following equation:

$$K = \frac{A}{S \exp{(VT/R)}} \qquad (1)$$

where K is the sublithospheric area per upwelling, A is the area of a particular plate, S is the number of observed hot spots on the plate, V is the velocity of the plate with respect to a fixed mesospheric frame, $T = t/g$ is the thickness of the plate divided by the global average lithospheric thickness, and R is the rate of ascent of the lithosphere–aesthenosphere boundary.

The values of the above parameters are listed in Table 1. The number of hot spots on each plate is as observed by Burke and Wilson[1]. Hot spots at or very near plate boundaries were omitted, however, because it would be unclear to which plate they belong, and because the lithosphere becomes very thin at rifts and mid-ocean ridges, giving a great penetration advantage to any upwellings underneath. Although other hot spot lists exist[18], this one was chosen as it is the most comprehensive and adheres most closely to the definition of hot spots used here. The velocities of the plates are as calculated by Minster and Jordan[19,20], and agree with other studies[21,22]. Plate thicknesses, as calculated from heat flow considerations of Sclater *et al.*[8] have been averaged over the area of each plate. These average values are in agreement with those calculated from other models[9–14,16]. The global average lithospheric thickness used was 120 km. The rate of ascent of the lithosphere–aesthenosphere boundary is as calculated by Withjack[6] as 2×10^{-8} cm s^{-1}, corresponding to basaltic magma, assumed constant throughout the Earth as hot spots are generally basaltic[1] worldwide. (If all of the magma entering the lithosphere is extruded[23] or otherwise accounted for[24], the basalt represents the bulk composition of the magma, and the above rate is to be used. If, however, the basalt does not represent the bulk composition of the magma, but is only a portion of the magma which is preferentially pushed through the lithosphere, R is greater, 1.5×10^{-7} cm s^{-1} for 5% basalt[6].) It is assumed here that regardless of the value chosen (or any intermediate), the average over the area of each plate remains constant throughout the Earth, and that this value will affect the normalization of the average distance between hot spots, $K^{1/2}$, but not the relative values of K for the various plates.

There are three anomalous plates. The Cocos plate is very small, and has one hot spot, making its hot spot density extremely high. However, so small a plate cannot present a statistically valid distribution, and so can be discounted. The Arabian plate is also very small and has several hot spots which may be associated with the rift system, and as such, cannot be used in this consideration.

The African plate has a large number of hot spots (31), and some authors[1,3,25] have claimed that it has been stationary with respect to the mantle convection pattern for the past 25 Myr. Minster *et al.*[19,20] have found the African plate to be moving only slowly about a rotation pole located within the plate. This rotation about an internal axis manifests itself as a velocity of zero at the pole, increasing with distance from the pole.

When $\ln{(A/S)}$ is plotted against Vt/R, a straight line is obtained, indicating the exponential dependence on Vt/R (Fig. 1). (Here, t is used rather than T for convenience. As they are proportional, the constant of proportionality, g, can be included in the axis scale, and still maintain a true representation of equation (1).) This dependence can be further verified by examining the limiting cases of velocity, thickness, and R. As $V\rightarrow0$, or $t\rightarrow0$, or $R\rightarrow\infty$, the lithosphere is effectively stripped away, and what remains is the sublithospheric area per upwelling, K. To be able to observe any of these limiting cases on the existing lithospheric plates would be an ideal test of equation (1). Clearly, $V\rightarrow0$ would be the most likely possibility. On Fig. 1, this would correspond to the y-intercept, at 3.3×10^6 km^2.

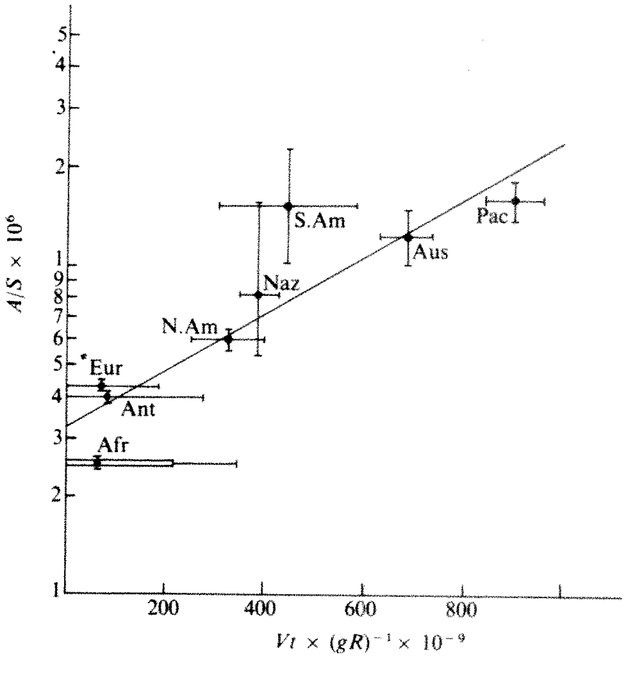

Fig. 1 Semi-logarithmic plot of (plate area/number of hot spots) versus (plate velocity × plate thickness). Horizontal error bars are minimum error associated with each plate from velocity and thickness errors. Vertical error bars represent ±1 hot spot on each plate. The double bar for Africa indicates the true range of Vt, as its pole of rotation lies within the plate. The line was plotted using a least squares fit, yielding an intercept at 3.3×10^6 km^2, with a correlation coefficient of 0.89, yielding a high degree of confidence (99.8%)[29,30] that a correlation exists.

0028-0836/80/380217—02$01.00

Table 1 Values of parameters in equation (1)

Plate	Hot spots	Plate area ($\times 10^{12}$ m^2)	Velocity ($\times 3.2 \times 10^{-10}$ m s^{-1})	Average thickness (km)	Vt	A/S ($\times 10^{12}$ m^2)
Eurasia	16	68.0	0.5	156	78	4.25
Australia	5	61.0	6.0	115	690	12.2
Pacific	7	113.0	9.0	100	900	16.1
North America	10	58.8	2.5	136	340	5.9
South America	3	46.2	3.1	144	446	15.3
Nazca	2	16.4	6.0	65	390	8.2
Africa	31	78.4	0–1.5	144	0–216	2.5
Antarctica	15	59.9	0.6	133	80	4.0

Africa's rotation pole lies within the plate. This causes significant variations in the velocity within the plate. These variations are represented by the double line on Fig. 1. If Africa had a uniformly zero velocity, it would plot as a point on the y-axis, close to the intercept of the line described by all of the plates (except Arabian and Cocos).

The penetration ability of upwellings depends exponentially on Vt/R because as a magma loses heat to the lithosphere, its temperature falls exponentially with respect to time[26] from its initial temperature to the ambient temperature of the lithosphere. If the time necessary for the magma to penetrate the lithosphere is longer than it takes to cool and solidify, there will be no hot spot on the surface. There will, however, be volcanism if the magma reaches the surface more quickly. Plate movement reduces the time available for penetration, while incremental increase of the thickness and magma entry rate increases, and decreases the time necessary for penetration to the surface, respectively. The statistical number of upwellings that reach the surface is proportional to ΔT (see Fig. 2), which decreases exponentially as time necessary to penetrate the lithosphere is increased. Note that as upwellings under any plate are not likely to be all of the same strength (radius, temperature), but are distributed about an average, a plate with characteristics putting it at τ_c will allow half of its upwellings to reach the surface. Plates which lie further to the right will allow less than half, those to the left will allow more.

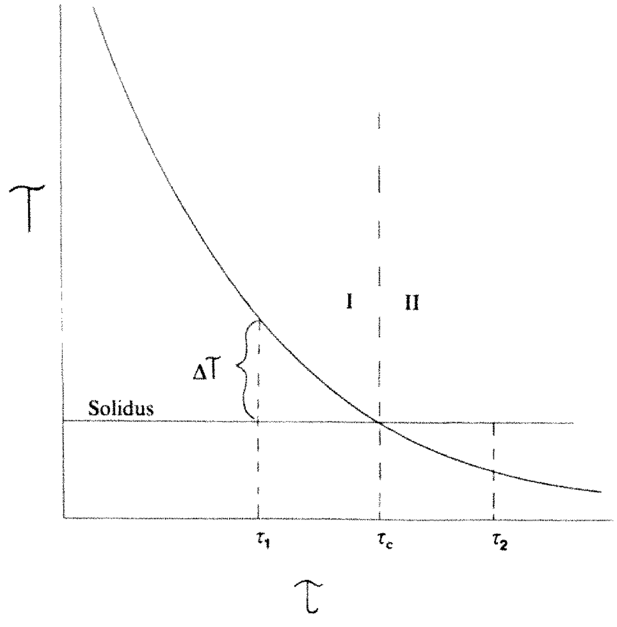

Fig. 2 Plot of temperature versus time for cooling magma. At points to the left of τ_c (region I), for example τ_1, the plate is thin and/or slow enough to allow penetration to the surface of an average upwelling. In region II, for example τ_2, average upwellings will not fully penetrate. At τ_c, half of the upwellings under the lithosphere will reach the surface. The statistical fraction of upwellings greater (I) or less (II) than 1/2 which reach the surface is proportional to ΔT.

The results show the sublithospheric area per upwelling to be 3.3×10^6 km^2, or 1,800 km between adjacent upwellings. The uniformity of the sublithospheric upwelling density may have implications regarding the origin of hot spots. It would seem to indicate a periodic physical[27], rather than random chemical[28], driving mechanism, making a model such as a stratified fluid instability plausible[27].

I thank Jason Morgan, Tom Crough, Eric Christofferson and Michael Carr for criticisms.

^{18}O/^{16}O variations in deep-sea carbonate shells from the Rise hydrothermal field

J. S. Killingley, W. H. Berger, K. C. MacDonald & W. A. Newman

Scripps Institution of Oceanography, La Jolla, California 92093

Active hydrothermal vents have recently been discovered[1] on the East Pacific Rise near 21° N (Fig. 1). Exotic benthic communities similar to those at the Galapagos vents[2] thrive around many of the vents. Some of these animals have calcium carbonate shells which presumably contain a temperature record in the oxygen isotopes of the carbonate. These provide an opportunity to investigate the temperature preferences of the organisms and, perhaps, the history of temperature variation near the vents. We report here stable oxygen and carbon isotope measurements made on clam shells and on a barnacle collected near the RISE vents from the submersible Alvin at a water depth of ~2,600 m (Fig. 1).

0028-0836/80/380218—04$01.00

The spreading centre here opens at a rate of 6 cm yr^{-1}, intermediate in the spectrum of spreading rates[3,4]. The rise crest consists of an uplifted axial zone 5-km wide and 80-m high[5]. The zone of most recent volcanism is between 600 and 1,400 m wide[6], and the hydrothermal vents occur within a strip only 300–500 m wide. They were mapped over a distance of 6.2 km along the spreading axis[1,7]. Three types of vents were observed. The first kind have low temperatures (10–20 °C), with clear to slightly milky hydrothermal fluids oozing out at rates of a few cm s^{-1} (ref. 8). The second ('white smokers') have plumes of hydrothermal fluids clouded by white precipitates issuing from distinct chimneys at rates of tens of cm s^{-1}. Temperatures[1] are between 100 and greater than 300 °C. The third ('black smokers') show the most vigorous activity ever observed at a sea floor hydrothermal vent. Waters blackened by sulphide precipitates jet out at rates of 1–5 m s^{-1} and at temperatures of at least 350 °C.

MacDonald and others[9] estimate that the heat loss associated with a single black smoker chimney is 2–8 times the total theoretical heat loss for a 1-km segment of ridge out to 1 Myr age to either side. This underlines the importance of hydrothermal circulation in the heat budget of mid-ocean ridges, but also requires that vents of this type be very short-lived. There was, therefore, considerable interest as to whether the isotopic composition of the carbonate shells might provide an indicator of temperature history.

The principal complication in attempting to link shell growth history to vent history is that some animals live several tens of metres away from the highest temperature vents, and that the lateral thermal gradients are extremely high. Water temperatures only 5–10 m away from the vents may be within 5 °C of ambient (2 °C), because the rapid discharge of low density ($\rho \sim 0.62$ g cm^{-3})[9] vent water draws in ambient water at a high rate.

We measured $^{18}O/^{16}O$ ratios on two shells from a new species of the vesicomyid clam, *Calyptogena*[10], and on scales from a new genus and species of stalked barnacle, *Neolepas zevinae*[11]. Clam shell valve ALV 909B-1 was empty, while ALV 914B-1 was from a living specimen (see Fig. 2). The clam shells were recovered from near a 'cool vent' in which water temperatures between 5 and 20 °C were measured. The barnacle was one of six removed from a rock (ALV 915) situated about 28 m from a 'black smoker'. Temperatures in this vent were not recorded because of instrument malfunction, but by analogy with similar vents the temperature of the actual water flow could reach 350 °C.

Samples for isotopic analysis, each about 0.5 mg, were removed with a 0.5 mm drill from points along the growth direction of a valve from each clam at approximately every 2 mm, starting at the shell lip and extending a few centimetres back to include all of the prismatic layer still present in each shell. In the older parts of the shells, this absent layer had presumably dissolved. A few samples were drilled from the nacreous layer towards the hinge. We expected that such sampling of the original prismatic layer, across growth bands, would reveal any extensive temperature fluctuations experienced by the mollusc, at least during the last few years of its life. The samples from the barnacle consisted of single scales removed at ~5 mm intervals along the peduncle, beginning at the base of the capitulum. The clam shells were found to be aragonite by X-ray diffraction, and *N. zevinae* hard parts are reportedly calcite[11].

All samples were heated at 250 °C for 30 min in vacuum, before being isotopically analysed for $\delta^{18}O$ and $\delta^{13}C$ (isotopic ratios are expressed as δ values (PDB) by the usual procedure[12]). The analytical precision was 0.07%.

Figure 3 shows the results of the isotopic measurements on the three specimens. We first consider the $\delta^{18}O$ ranges observed. The $\delta^{18}O$ (PDB) values for clam A (909B1 empty) range from 3.2 to 4.3‰; those for clam B (914B1 live) from 3.0 to 4.3‰; and those for the barnacle from 3.8 to 4.4‰. (Only the ranges of values measured on the clam prismatic layers are considered here because of possible non-equilibrium precipitation of the nacreous layer.)

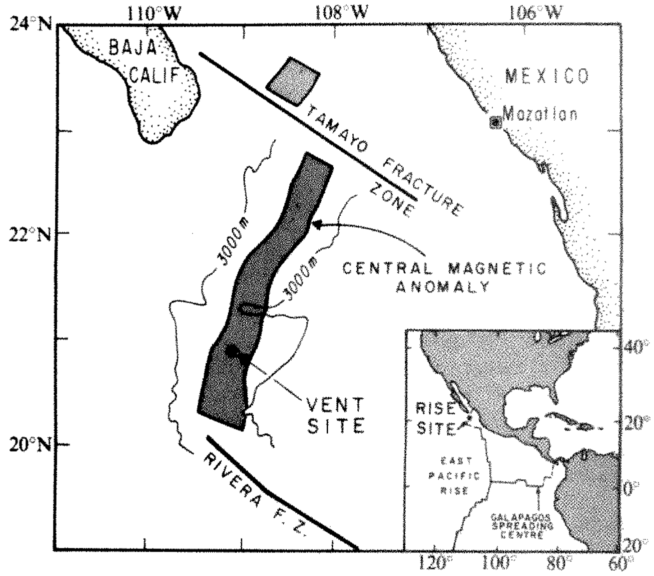

Fig. 1 Regional map.

The measured $\delta^{18}O$ maxima from each shell are essentially the same, which suggests that they correspond to the temperature minimum (the ambient seawater temperature). Although a temperature corresponding to the maximum $\delta^{18}O$ value can be calculated, there are three sources of error: (1) there is disagreement of about 0.5° at near-zero temperatures between different palaeotemperature equations; (2) the difference between the isotopic fractionation behaviour of calcite (on which palaeotemperature equations are based) and that of aragonite is not known; and (3) the isotopic composition of the ambient seawater is not known exactly.

The empirical palaeotemperature equation has the form[13,14]:

$$T(°C) = A - B(\delta^{18}O_c - \delta^{18}O_w) + C(\delta^{18}O_c - \delta^{18}O_w)^2$$

where A, B, C are constants. The isotopic value of calcite is $\delta^{18}O_c$ and $\delta^{18}O_w$ is the isotopic composition of the water from which the calcite precipitated. We assumed a value for $\delta^{18}O_w$ of −0.3‰ for the water in which the clams grew[15] (vent-water composition is not important in this context) and found for the maximum $\delta^{18}O_c$ value (4.3‰) that the calculated temperature (0 °C ± 0.3) was ~2 °C lower than ambient. (Tarutani *et al.*[16] experimentally determined the fractionation between inorganically precipitated calcite and aragonite as 0.6‰ at 25 °C which, if applicable at low temperatures, would lead to a calculated minimum value of 1.8 °C ± 0.4, which is a more reasonable value.) In spite of uncertainties in the actual temperatures, a good estimate can be made of the temperature difference corresponding to the $\delta^{18}O$ range from 3.0 to 4.3‰. This difference is ~4.5 °C, so that if the coldest temperature is 2 °C, then the clams record a range from 2 to 6.5 °C. It has been observed that the clams and some other animals found in similar vent regions of the Galápagos Rift occur some distance from the actual vent, apparently living in water close to ambient temperature[17]. From our data, it seems that the clams experience periods when the water is warmed by geothermal activity to at least 4 °C above ambient temperature. This represents a minimum estimate, for we do not know the upper temperature limit at which the animal ceases to grow shell. A statistical study of shell rim material from a large number of clams might, however, provide clues to the upper tolerance limits for growth.

Five of the $\delta^{18}O$ values measured on the calcitic scales from the barnacle are in the range 4.2±0.2. Ignoring the palaeotemperature equation, this suggests that 4.2‰ corresponds to the ambient water temperature of 2 °C as before, implying that the water/carbonate ^{18}O fractionation is similar for calcite and aragonite at these low temperatures. However, coincidental agreement of maximum δ^{18}values for the two taxa, resulting from different vital fractionation effects, cannot be ruled out.

Besides the ranges of the δ^{18}O values, the nature of the sequences is of interest. It seems that the progression of values in the clam shells shows coherence over a distance of some 10 mm, which presumably corresponds to a period of the order of one year (see below). There may be an indication of cyclicity in clam B, reminiscent of seasonal variations. It is perhaps not entirely unreasonable to expect some types of cyclicity in vent activity. Earth tides have shown to be important in triggering earthquake activity on Galápagos[18] and elsewhere[19-21]. Thus one might expect that the strain produced by Earth tides could affect any diverted flow through cracks by changing the size and linkage of such cracks. Lunar temperature cycles could result from such a mechanism, and the growth lines observed in the clams (Fig. 2) might be profitably studied under this aspect.

We next consider the carbon isotope values. Expected δ^{13}C values for equilibrium precipitation at this site are between 1 and 1.5‰ (ref. 22) if we assume an ambient δ^{13}C of close to 0‰ (refs 23, 24). Observed ranges are −0.5 to −2‰ for the barnacle calcite, 3.5–5‰ for the prismatic layer of clam A and 1–2‰ for that of clam B. The nacreous 'repair' material in both clams is isotopically lighter than the prismatic layer.

Only the clam B record seems to show near-equilibrium values, although, in fact, equilibrium values for aragonite are not well established. Rubinson and Clayton[25] report a fractionation between aragonite and calcite at 25 °C of 1.8‰, which if similar at 2 °C, would suggest that the δ^{13}C value should be ~3‰ at equilibrium. Hence, the clam A record may be closer to equilibrium. In either case, the pronounced difference between the δ^{13}C value of clam A and clam B is puzzling. One might suspect interference from organic matter in the analysis. However, both clams were treated in the same way, and it is not clear how a difference would be introduced through treatment.

If clam A values are near equilibrium, the lighter clam B values could be due to metabolic ^{12}C enrichment or vent-carbon effects, or both. Vent-carbon is expected to be depleted in ^{13}C compared to ambient bottom water, in analogy to volcanogenic carbon. The light values of the barnacle calcite must be considered in the same light.

To interpret the isotopic record in terms of history, we need a time scale. An estimated age of 6.5 yr from radionuclide ratios has been reported for a vesicomyid clam from the Galápagos Rise hot spring field[26]. Presumably, this estimate yields the correct scale for our clam samples. However, the fact that these clams are aragonitic may lead to erroneously young ages if substantial dissolution has occurred.

A valve of clam B (collected live) was cut in the growth direction to expose a cross-section (Fig. 2*a*). The shell structure from the lip (most recent growth) to approximately half way to the hinge consists of the sequential growth bands typical of molluscan prismatic growth. The remainder of the shell is a nacreous layer and is all that remains of the older portion of the shell where the prismatic layer has been dissolved away, due to the fact that the shells grow below the aragonite compensation depth for this region[27].

The mass of the nacreous growth is estimated to be roughly one-half of the mass of the remaining original growth. The nacre presumably also suffered attack and is likewise partly missing, being in turn made up for from below. Thus, a straight radiometric age determination on this specimen could be approximately half the true age. We have measured the average

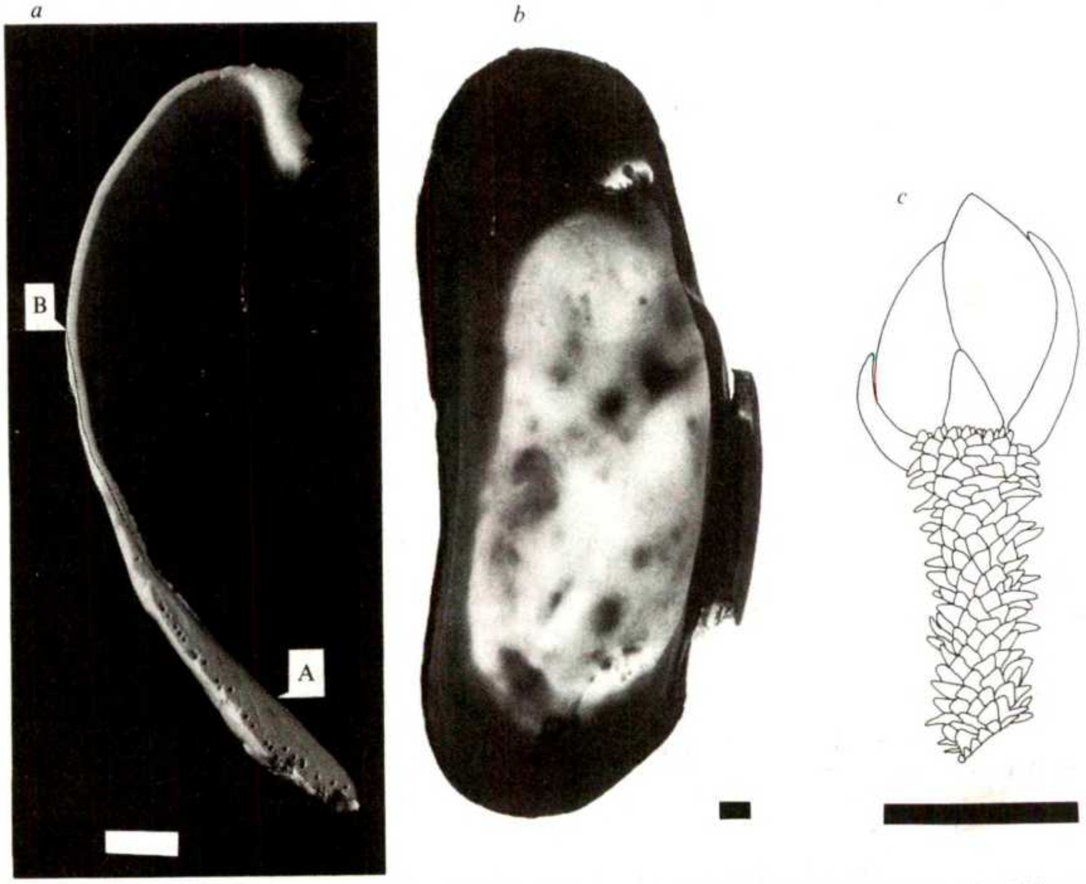

Fig. 2 *a*, Cross-section of clam shell (dorsal margin up) from a living *Calyptogena*, ALV 914 B-1 showing the decreasing thickness of the outer, prismatic, layer until none remains, dorso-laterally beginning at B. The inner secretion of nacre extends from A and increases in thickness until at B it constitutes the whole of the shell wall. Scale bar, 1 cm. (Some of the sample drill holes are apparent in the photograph.) *b*, Shell (dorsal margin to right) of a dead *Calyptogena*, ALV 909 B-1 illuminated with strong light from below. The light area represent secondary, nacreous, structure, while the opaque area indicates regions where all or part of the upper prismatic layer remains. Scale bar, 1 cm. *c*, Lateral view of the barnacle, *Neolepas zevinae*, ALV 915-rock 4 (first paratype, British Museum (Natural History) reg. no. 1979·209). Note that the peduncle is clad with irregular whorls of scales. New whorls are added at the junction between the capitulum and the peduncle so that scales grade in age from the oldest at the point of attachment to the youngest immediately below the capitulum. Scale bar, 1 cm long.

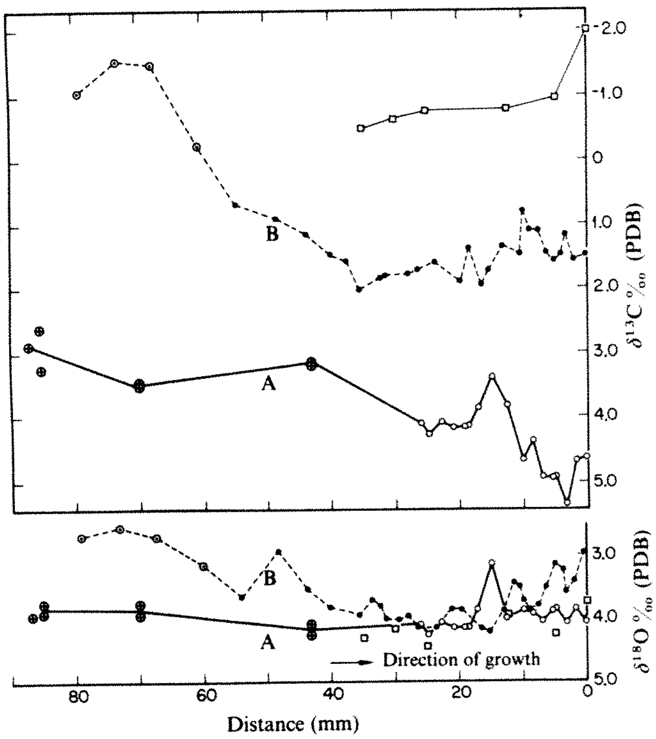

Fig. 3 $\delta^{18}O$ and $\delta^{13}C$ variations as a function of shell growth. Dead clam (A) Calyptogena (ALV909B-1); ○, prismatic growth; ⊕, nacreous growth. □, Barnacle *N. zevinae* (distances for scales analysed are from capitulum to the point of attachment): holotype USNM cat. no. 172581. Living clam (B) (ALV914B-1): ●, prismatic growth; ⊙, nacreous growth. Distances are from the margin of the shell (clam) and from the base of the capitulum (barnacle).

rate of dissolution (about 15 mg cm^{-2} yr^{-1}) of clam fragments by suspending them at a depth of 2,700 m (lat. 0.0°0.2′ N, long. 152°13.0′ W) for 4 months. This rate of dissolution implies that an empty whole shell would dissolve in ~25 yr in the vent region.

Reactivation of a vent after dormancy might be indicated by clam assemblages in various states of preservation. Incidentally, the fact that vesicomyid clams have not been reported from the North Atlantic Ridge crest area, despite the excellent conditions for aragonite preservation there[27], may be in accord with the more slowly spreading rates, which would not be able to support the enormous heat loss associated with high-temperature, high-velocity RISE-type vents.

Our results show that the clams and the barnacle analysed grew at ambient to slightly higher-than ambient temperatures.

Hydrothermal leaks in the vicinity of the vents may influence the stable isotope record of the shells, as well as their growth, and organic carbon of chemosynthetic origin[28] may do likewise. Future work might focus on parallel examination of live-collected clams and other shelled organisms, to separate ambient from individual variations. The possibility of cyclicity in ambient conditions seems worth investigating; if cyclicity exists, it would provide instant age scales for carbonate-secreting organisms.

We thank F. N. Spiess and R. R. Hessler for samples and for encouragement, also R. A. Knox for arranging the dissolution experiment, and M. Kastner for criticisms. This work was supported by the NSF, Oceanography Section: grant OCE78-25587.

Concentrations of ^{113m}Cd in the marine environment

V. E. Noshkin, K. M. Wong, R. J. Eagle & D. L. Anglin

Environmental Sciences Division, Lawrence Livermore Laboratory, University of California, Livermore, California 94550

Reports on the detection of ^{113m}Cd in any type of environmental sample have been rare. The 113 mass chain yield is small relative to other longer-lived fission products, such as ^{90}Sr and ^{137}Cs, produced from uranium, plutonium and thorium fissions[1]. Also, only a small fraction of the 113 chain yield decays to ^{113m}Cd (ref. 2). Salter[3] estimated that the ^{113m}Cd/^{90}Sr activity quotient in thermonuclear fission should be 0.003. He stated that "this ratio is in good agreement with data from a few samples measured in the northern hemisphere prior to 1962 which have no ^{109}Cd". This, to our knowledge, was the first report of the detection of fission-produced ^{113m}Cd in the environment. Salter[3] also calculated that 0.062 MCi of ^{113m}Cd and 0.25 MCi of ^{109}Cd were produced by activation during the atmospheric detonation of the 1.4-megaton Starfish device on 9 July 1962 over Johnston Atoll. As both ^{109}Cd and ^{113m}Cd are produced during neutron activation of stable cadmium, and ^{109}Cd is not a fission product, the last part of Salter's statement is significant. The absence of ^{109}Cd in samples collected before 1962 indicates that all nuclear testing before this time, which included all tests conducted at Enewetak and Bikini Atolls in the Marshall Islands, could have generated ^{113m}Cd only as a fission product. It is therefore important to recognize that ^{113m}Cd could be present in other environments contaminated with fission product wastes discharged to the aquatic environment from other nuclear facilities. ^{113m}Cd has a half life[4] of 14.6 ± 0.1 yr and decays predominantly by beta-particle emission. We present here a preliminary report of ^{113m}Cd concentrations measured in sediment and tissue samples of marine organisms collected around different atolls in the Marshall Islands.

A series of pooled and individual fish liver and sediment samples were selected for analysis. It has been well documented that stable cadmium is concentrated by the liver of fish[5,6]. Liver analysis offered the most sensitive test for presence of ^{113m}Cd in the marine environment, especially at those atolls where only global fallout background concentrations could be anticipated in the environment. Gamma spectrometry was used to measure ^{113m}Cd ($E\gamma = 263.7 \pm 0.3$ keV; branching intensity 2.3×10^{-4})[7] in large samples of ashed liver when activity levels were high, otherwise ^{113m}Cd was measured on low-background beta counters following radiochemical separation of cadmium from other radioelements in the samples. The methods used to identify and detect ^{113m}Cd in these samples are reported elsewhere[8].

Concentrations of ^{113m}Cd and other radionuclides detected in the samples are shown in Table 1. Some ^{113m}Cd measurements were made during the 1972–73 radiological survey of Enewetak Atoll. As the relevance of these results has been overlooked,

† Viscera sample includes all internal organs and gut contents which contain undigested sediment. Concentrations are biased by higher concentrations of transuranics, ^{55}Fe and others in sediment.

they are abstracted from the survey report[9] and shown in Table 2.

^{113m}Cd was detected in all samples collected between 1972 and 1979 from Bikini and Enewetak Atolls and in fish liver samples from other atolls in the Marshall Islands, some of which were in the paths of close-in fallout debris from the nuclear tests conducted at Bikini and Enewetak. Radionuclides persist in these environments 21 yr after the last nuclear explosion at the atolls in 1958. ^{113m}Cd concentration was found to be lower in the surface sediment layer compared to ^{60}Co, ^{137}Cs, $^{239+240}$Pu, ^{241}Am and ^{207}Bi, but it exceeds the concentrations of these radionuclides in the liver samples of Bikini tuna, shark and snapper by at least one order of magnitude. In the liver samples of Bikini reef species, ^{113m}Cd concentrations are at present comparable to ^{60}Co and greatly exceed the concentrations of the other radionuclides we have measured so far. The concentrations of ^{113m}Cd in the liver samples of mullet, a herbivore, are much less than the concentrations detected in the pelagic carnivores at Bikini. This comparison suggests the concentration of ^{113m}Cd is greater in representative species from higher trophic levels. Fish from Bikini seem to contain more ^{113m}Cd in the liver than fish from Enewetak lagoon. Concentrations in the flesh of bonito from Enewetak Atoll are much lower than concentrations in the liver samples of the fish. This finding would have been predicted from the studies of stable cadmium distributions in fish. In 1979 grey reef sharks were taken from different quadrants of Enewetak lagoon (distinguished by the different island numbers in Table 1). Very different levels of radionuclides are associated with the lagoon sediments in each quadrant. There seems to be no significant relationship between

^{113m}Cd concentrations in the liver and the geographical region from which the sharks were caught. Although sharks in local regions of the lagoon may encounter very different levels of radioactivity, they appear to act more as 'averagers' as they probably travel into and out of the more or less radioactive parts of the lagoon continuously during their life.

Close-in fallout contamination is still evident in the marine environment at Rongelap Atoll, where concentrations of ^{113m}Cd in mullet liver samples are even higher than the levels detected in mullet collected from the eastern half of Bikini Atoll. The lowest concentration of ^{113m}Cd measured was ~0.2 pCi per dry weight in the liver of reef species from the atolls of Utirik, Ujelang and Bikar. ^{137}Cs activities in the flesh of these fish were in the range of fallout concentrations detected in the flesh of mullet samples collected in 1979 from North Carolina, USA (unpublished data). Therefore, the ^{113m}Cd concentrations in the atoll samples are probably representative of the levels expected at these latitudes from global fallout deposition.

It is not clear at this point if the current absence of reports of ^{113m}Cd concentrations indicates this radionuclide was measured but not detected, or that insufficient effort has so far been made to evaluate this radionuclide in environments receiving fission product wastes. Although production of ^{113m}Cd during the fission event may be low, we have found that this radionuclide persists in the environment and is significantly concentrated in the liver of fish at the atolls. Concentrations presently exceed the levels of most other long-lived man-made radionuclides in liver by orders of magnitude. We have not yet generated sufficient data to evaluate its radiological significance in major dietary items at the Marshall Islands but these analyses are one of our main priorities. Stable cadmium is known to be concentrated by man in the kidney and liver[7]. As ^{113m}Cd will follow stable cadmium through the food chain—it decays by emitting energetic beta particles ($E_{max} = 0.58$ MeV)—and has a relatively long half life, the integrated radiological dose to man from ^{113m}Cd ingestion will be carefully assessed at the Marshall Islands and should also be assessed at other sites where contamination by this radionuclide may be suspected.

We thank Dr D. R. Nelson for samples of shark caught during November–December 1979 at Enewetak Atoll. D.L.A. was a summer participant supported by the Associated Western Universities. This work was performed under the auspices of the US Department of Energy, contract number W-7405-ENG-48.

Recent studies of locomotion in red kangaroos (*Megaleia rufa*, 18–28 kg)[1] and Australian hopping mice (*Notomys cervinus*, 36.6 g)[2] have indicated that over a certain range of speeds the energetic cost of bipedal hopping locomotion may become independent of speed. As much as 70% of the decrement in kinetic energy which takes place when the kangaroo lands may be stored in elastic elements and used to propel the kangaroo upwards and forwards as it takes off (leaving only 30% to be added by the muscles)[3,4]. Presumably, this same phenomenon could be exploited by all bipedal hopping mammals and it seems possible that at high speeds this specialized mode of locomotion could result in large energetic savings when compared with the costs incurred by a similarly sized quadruped running at the same speed. This hypothetical lower cost of locomotion has been invoked as an explanation for the rather common occurrence of bipedal hoppers among desert and plains dwelling mammals, as it might substantially reduce the energetic cost of foraging, or travelling, for animals utilizing widely dispersed resources[5–7]. The purpose of the present study was to extend the assessment of the metabolic expense of bipedal hopping to a broader range of body sizes and mammalian taxa. Using indirect calorimetry we measured the cost of locomotion for three bipedal hopping eutherians (0.03–3.0 kg) and one bipedal hopping marsupial (1.1 kg). When properly trained for sustained running, none of the three species deviated from the expected quadrupedal pattern relating cost of locomotion to running speed, even while running fully bipedally. Bipedality must therefore be associated with benefits other than those related to the energetic costs of locomotion.

We trained two spring hares (*Pedetes capensis*, Rodentia; Pedetidae, average weight 3.0 kg), two rat kangaroos (*Bettongia penicillata*, Marsupialia; Macropodidae, average weight 1.1 kg), eight desert kangaroo rats (*Dipodomys deserti*, Rodentia; Heteromyidae, average weight 104 g) and one Merriam's kangaroo rat (*Dipodomys merriami*, 32 g) to hop on a treadmill while we measured their oxygen consumption. We considered the animals 'trained' when they would sustain one gait and position on the treadmill—5 min for the smaller *Dipodomys* and 20 min for the larger species—over a range of speeds. Naive and poorly trained animals would oscillate forwards and backwards along the treadmill at all but a few preferred speeds; these animals also frequently altered their gait when moving from the back to the front of the tread.

Rates of oxygen consumption were measured by enclosing the animal in a Plexiglas chamber which either slid along the tread (*Pedetes* and *Bettongia*) or enclosed it (*Dipodomys*). Air was metered through the box (170 l min^{-1} STP for *Pedetes* and *Bettongia* and 7 l min^{-1} STP for *Dipodomys*). The difference in oxygen concentration (ΔO_2) between dry air entering and leaving the box was measured using an oxygen analyser (Applied Electrochemistry S-3A for the *Pedetes* and *Bettongia* and Taylor Servomex 0–272 for the *Dipodomys*). Rate of oxygen ($\dot{V}O_2$) consumption was calculated assuming a respiratory quotient of 0.8 by multiplying flow through the chamber by ΔO_2 and dividing by 0.9581 as described by Tucker[8] for a similar system. The chambers were checked for leaks of exhaled air by decreasing the flow by 30% as the $\dot{V}O_2$ was monitored. This procedure should increase the magnitude of any loss of exhaled air: no difference was found between $\dot{V}O_2$ measured at either flow rate. In *Pedetes* and *Bettongia*, the rate of anaerobic glycolysis was determined by measuring the change in blood lactate concentration (using a Boehringer-Mannheim lactate test kit) over the timed interval of the run; comparison of resting to running levels of lactate production revealed no significant increase over the range of speeds for which $\dot{V}O_2$ was measured. Anaerobic glycolysis was not assayed in *Dipodomys* due to the adverse effect of blood sampling procedures on treadmill behaviour.

Rates of oxygen consumption increased linearly with speed in all four species of hopping mammals over a wide range of speeds which included the transition from completely quadrupedal to

0028-0836/80/380223—02$01.00

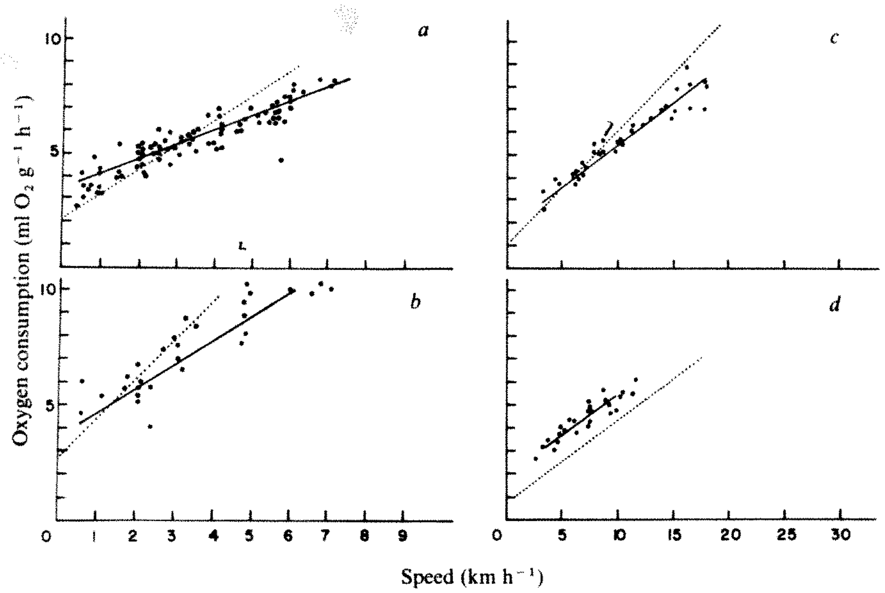

Fig. 1 Rate of oxygen consumption as a function of speed for four small species of bipedal hopping mammals. All values are for fully trained animals (moving at a constant gait and speed, that is, they used one gait and kept their position on the tread constant). Solid lines represent the least squares regression for the linear portion of each graph, where

$\dot{V}O_2$ (ml O_2 per g h) = slope × speed (km h^{-1}) + y intercept

(*a*) *D. deserti*, 104 g, $N = 8$. $\dot{V}O_2 = 0.66 \times \text{speed} + 3.25$. $r^2 = 0.85$, $n = 95$, $P < 0.001$

(*b*) *D. merriami*, 32 g, $N = 1$. $\dot{V}O_2 = 1.1 \times \text{speed} + 3.67$. $r^2 = 0.50$, $n = 25$, $P < 0.005$

(*c*) *B. penicillata*, 1.1 kg, $N = 2$. $\dot{V}O_2 = 0.39 \times \text{speed} + 1.74$. $r^2 = 0.88$, $n = 33$, $P < 0.001$

(*d*) *P. capensis*, 3.0 kg, $N = 2$. $\dot{V}O_2 = 0.34 \times \text{speed} + 2.04$. $r^2 = 0.67$, $n = 26$, $P < 0.001$

Dotted lines represent the predicted oxygen consumption for a running quadrupedal mammal of the same body size using the equation of Taylor, Schmidt-Nielsen and Raab[15]. Slopes of all four empirical regressions are not significantly different from those predicted (*t*-tests, $P < 0.05$).

completely bipedal locomotion (transition speeds were 3–5 km h^{-1} for both *Pedetes* and *Bettongia*, 2–3 km h^{-1} for *D. deserti* and 1.5–2.5 km h^{-1} for *D. merriami*). These speeds also encompassed the normal foraging speeds of both *D. merriami* (average 3.2 km h^{-1}) and *D. deserti* (6.33 km h^{-1})[9]; foraging speeds of *Pedetes* and *Bettongia* are unknown. This rate of increase was very similar to that predicted for a quadrupedal mammal of the same mass (dotted lines in Fig. 1). Although at higher speeds the predicted values are greater than those observed for hopping bipeds (Fig. 1*a–c*), those slight differences are not statistically significant and it seems unlikely that they would confer any biological advantage to bipeds. Plots of $\dot{V}O_2$ against speed for untrained animals gave a sigmoidal relationship similar to that reported by Dawson[2] for a 36.6-g hopping mouse. However, as training proceeded, our animals began to maintain a constant gait and eventually they would remain at the same tread location (near the front of the tread) throughout the run. In the latter conditions, the relationship between $\dot{V}O_2$ and speed was linear (Fig. 1), not sigmoidal. Apparently, the sigmoidal relationship between $\dot{V}O_2$ and speed was an artefact of the fore and aft motion of poorly trained animals; these animals were probably not in a steady state.

We conclude that hopping is not an energetically cheaper way to move for small hoppers (<3 kg) than quadrupedal locomotion. As the locomotory costs of small marsupial and rodent hoppers are similar to those of quadrupedal mammals of comparable body mass, we are left with two questions, one functional and one evolutionary. First, we have no immediate explanation for the differences in locomotory energetics of small (this study) and large (red kangaroos) hoppers; however, it is apparent that those differences do exist. Of the six species of small bipedal hoppers for which the energetic cost of locomotion has now been determined, only one, *Notomys cervinus*, shows any tendency towards an independence of cost and speed. Moreover, because a congener, *Notomys alexis*[10], fails to show any evidence of an uncoupling of speed and energetic cost, it seems plausible that the unique pattern shown by *N. cervinus* may reflect training problems similar to those encountered in the present study. The red kangaroo data, on the other hand, do not seem to be methodological artefacts, and therefore the differences between large and small hoppers seem valid. Second, if there is no energetic advantage for small animals to hop, why do they do so? The majority of bipedal hopping mammals are much smaller than *Megaleia*, and presumably would have locomotory costs qualitatively similar to the four species reported here. Thus, it would seem that the advantage of bipedal hopping locomotion does not, at least for most species, lie within the realm of locomotory energetics.

Our findings do not support models of small mammal foraging behaviour and resource partitioning based on the assumption that the locomotory energetics of small hopping bipeds differ appreciably from those of small quadrupeds. Small hopping bipeds display a wide variety of behavioural traits (for example, vertical leaping, rapid changes in direction) which suggest that the chief benefit of this mode of locomotion is related to enhancement of abilities to escape predation[11,12]. These traits are accompanied by enlargement of both the visual and auditory apparatus; this further suggests that the morphology of small hopping bipeds has been moulded by their increased exposure to predation when foraging in the open areas of habitats with sparse vegetation[13,14]. Thus, it seems most likely that the bipedal hopping mode of locomotion in small mammals has evolved as a result of its advantages for the avoidance of predatory attacks and not as an energetic strategy associated with foraging on dispersed resources.

Direct evidence of sudden rise in fetal corticoids late in human gestation

Montserrat deM Fencl, Robert J. Stillman, Jane Cohen & Dan Tulchinsky

Department of Obstetrics and Gynecology, Harvard Medical School, and the Endocrine Laboratory, Boston Hospital for Women, Boston, Massachusetts 02115

Glucocorticoids accelerate fetal lung maturation in all mammals studied[1], and in some species, such as goat and sheep, concentrations of fetal cortisol increase sharply before term, bringing about a train of events leading to parturition[2]. Studies of cortisol in the umbilical cord blood have revealed no such increase at the end of human pregnancy. But information obtained in that way is difficult to interpret because much of the fetal cortisol is of maternal origin[3,4] and its concentration, if sampled at delivery, is affected by maternal stress[5]. These problems can be avoided to some extent by studying other fetal corticoids. Corticosterone sulphate (once called compound B, and abbreviated to BS) is produced by fetal adrenal glands[6] and is present in greater concentrations in human fetal plasma than in maternal plasma[7]. It is not hydrolysed by the placental sulphatases and is a poor substrate for placental 11 β-hydroxysteroid dehydrogenase[8]. We report here confirmation that the bulk of maternal BS originates from the fetus, and that its concentration increases suddenly at term.

We measured BS in maternal and fetal fluids of normal pregnant women, women carrying anencephalic fetuses and a pregnant woman whose adrenals had been removed 5 yr earlier because she had Cushing syndrome. Samples of plasma, urine and amniotic fluid were assayed for BS after solvolysis and chromatography as before[9]. Student's *t* test was used for statistical evaluations. As Fig. 1 shows, the mean (±s.e.) concentration of BS in the plasma of non-pregnant women was 2.8 ± 0.3 ng ml^{-1}; at mid-pregnancy (21–32 weeks) it increased to 6.7 ± 0.5 ng ml^{-1}, and at term (38–40 weeks) it was about three times greater at 16.0 ± 3.2 ng ml^{-1} ($P < 0.01$). A further increase was observed in women in labour (26.4 ± 6.3 ng ml^{-1}). During labour, those carrying anencephalic fetuses had a significantly lower plasma BS than normal (8.3 ± 0.4 ng ml^{-1}; $P < 0.02$). In the pregnant woman with no adrenals, the concentration of BS in the plasma, which was monitored throughout pregnancy, increased gradually during the second and third trimester, the most pronounced increase occurring in the last week before spontaneous labour began. Before delivery, her plasma BS was within the range seen at term in a normal pregnancy, and there was no further increase during labour.

Quantities of BS in 24-h urine collections of non-pregnant and pregnant women are shown in Fig. 2. The pattern of increase in urinary excretion of BS during pregnancy was similar to that in maternal blood. Serial measurements of BS in the urine of the pregnant woman with no adrenals increased sharply during the week preceding delivery. Excretion of BS by this patient at term reached the range seen in normal pregnancies. Figure 3 shows that in deliveries at mid-pregnancy there was only slightly less BS in umbilical cord blood than at term (54.5 ± 2.9 compared with 62.7 ± 6.7 ng ml^{-1}; $P > 0.1$). In the cord plasma of the infant of the woman with no adrenals, BS was normal (60 ng ml^{-1}). However, in anencephalic fetuses at term, the mean concentration of BS in cord blood (15.9 ± 3.0 ng ml^{-1}) was one quarter of that in normal infants at term ($P < 0.001$). In the woman without adrenals, the amniotic fluid, sampled at vaginal delivery, contained BS within the range of normal pregnancies (42.6 ng ml^{-1}), whereas in two women carrying anencephalic fetuses, BS was abnormally low in the amniotic fluid (3.9 and 6.2 ng ml^{-1}).

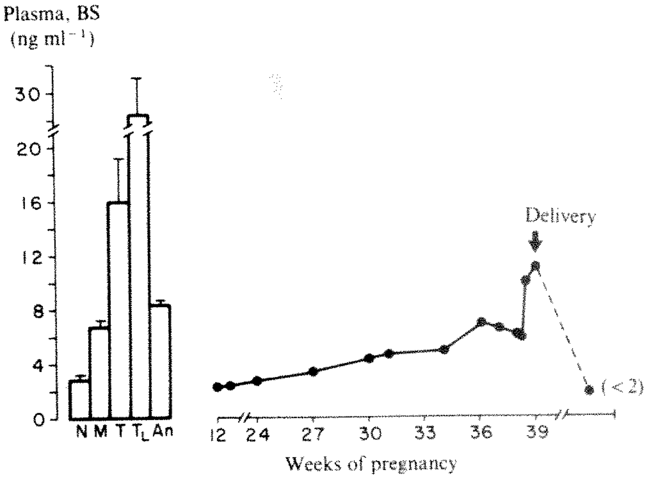

Fig. 1 Corticosterone sulphate (BS) concentrations in the maternal plasma of a woman with no adrenals at various stages of her pregnancy (●). Bars indicate concentration (mean ±s.e.) of BS in plasma of normal non-pregnant (N), and pregnant women at mid-pregnancy (M), term (T), and term in labour (T_L); and in women carrying anencephalic fetuses in labour at term (An). Replacement therapy with fludrocortisone (0.1 mg d^{-1}) and prednisone (7.5 mg d^{-1}) was given to the patient with no adrenals throughout pregnancy. BS was measured after solvolysis as corticosterone by radioimmunoassay (RIA), using an antibody prepared against cortisol-21-hemisuccinate-BSA; the antibody cross-reacted with cortisol (150 %), cortisone (2%), deoxycorticosterone (17%), prednisone (12%), prednisolone (19%), and 17α-hydroxyprogesterone (24%). All these compounds were separated by chromatography before RIA[9]. There was less than 1% cross-reactivity with all other steroids tested. Blank values were always undetectable (<20 pg). The interassay coefficient of variation was less than 15%. Recoveries after extraction and chromatography were 77.7 ± 10.4 (s.d.). In calculating the concentration of BS, corrections were made for differences in molecular weight between conjugated and unconjugated steroids. No. of subjects: N, 8; M, 14; T, 8; T_L, 5; An, 7.

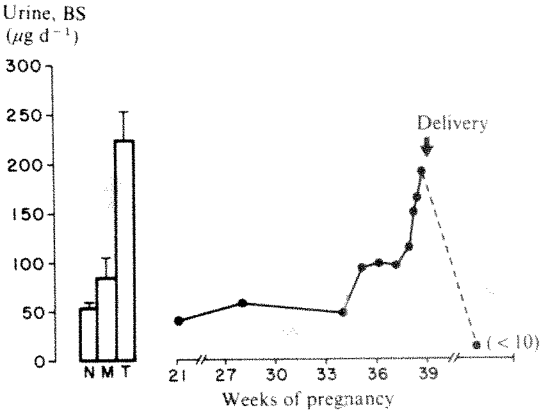

Fig. 2 Corticosterone sulphate (BS) concentrations in the urine of a woman with no adrenals at various stages of her pregnancy (●). Bars indicate values (mean ±s.e.) of BS in the urine of normal non-pregnant (N), and pregnant women at mid-pregnancy (M), and at term (T). No. of subjects: N, 6; M, 3; T, 6.

These data indicate that at least two thirds of BS in the maternal compartment at term is derived from the fetus: in women carrying anencephalic fetuses, concentrations of plasma BS at delivery were one third, and in umbilical cord plasma one quarter of that in normal pregnancies. Because the placenta cannot produce or metabolize BS, the increase in urinary
plasma BS throughout pregnancy indicates increased
tion by the fetal adrenal. This was confirmed because
with no adrenals had normal concentrations of
plasma BS which increased during the last

0028-0836/80/380225—02$01.00

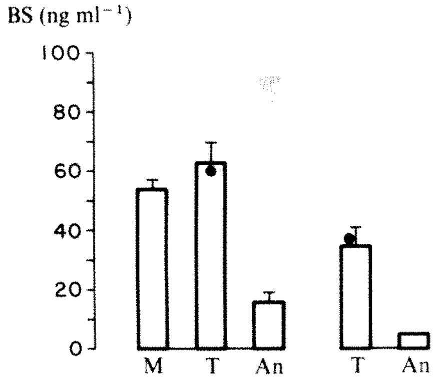

Fig. 3 Corticosterone sulphate (BS) concentrations in umbilical cord plasma and amniotic fluid of a pregnant woman with no adrenals (●). Bars indicate concentrations (mean ±s.e.) of BS in umbilical cord plasma (left) and amniotic fluid (right) of normal women at mid-pregnancy (M), and term (T), and in women carrying anencephalic fetuses in labour (An). No. of subjects umbilical cord: M, 7; T, 8; An, 6. No. for amniotic fluid: T, 8; An, 2.

most pronounced increase during the week preceding spontaneous labour.

The data obtained from the pregnant woman without adrenals, as well as the normal pregnant women, suggest that the production of BS by the fetal adrenals increases markedly near term. These results are compatible with the ultrastructural changes observed in the outer definitive zone of the fetal adrenal at term[10], and the increase in the size of the human fetal adrenal towards term[11]. Furthermore, conjugated cortisol also rises in amniotic fluid towards term[12], possibly a consequence of an increase in urinary excretion of this steroid by the fetus[9]. Thus, it is likely that the increased output of the fetal adrenal near term is not limited to BS but includes other corticosteroids. The fact that concentrations of BS in the umbilical cord plasma of normal infants at term were insignificantly higher than at mid-term, similar to results reported for other corticosteroids, does not exclude an increase in fetal adrenal production near term, for the rate of fetal metabolic clearance of BS into the maternal circulation is likely to be greater in late than in mid-pregnancy.

In humans, corticosteroids have not been implicated in the mechanisms leading to labour; however, they may well have a role in initiating other physiological changes, among them fetal lung maturation. In some species, such as the rabbit, the time of augmented surfactant production is preceded by an increase in fetal circulating unbound cortisol[13], together with an enhancement in the capacity of the lung to convert cortisone to cortisol[14]. Unconjugated corticosterone is a potent glucocorticoid that binds to specific lung receptors in the human[1], and in the rabbit it induces production of lung surfactant[15]. However, it is not known whether corticosterone in its conjugated form binds directly to lung receptors, or whether it can be hydrolysed by lung sulphatases, thus becoming biologically active. Further studies are necessary to clarify whether there is a direct association between increased fetal adrenal corticoid output, as determined by maternal concentrations of BS, and the status of fetal lung maturation, determined by analysis of concentrations of surfactant in the amniotic fluid.

Expulsion of *Nippostrongylus brasiliensis* by mice deficient in mast cells

Cynthia L. Uber*, Richard L. Roth† & David A. Levy†

Department of Epidemiology* and Department of Biochemistry†, The Johns Hopkins University, School of Hygiene and Public Health, 615 North Wolfe Street, Baltimore, Maryland 21205

Expulsion of the intestinal helminth, *Nippostrongylus brasiliensis*, occurs spontaneously about 2 weeks after a primary infection of rats[1] and mice[2]. Cellular changes in the small intestine coincident with the period of expulsion have suggested several mechanisms by which this 'self-cure' may be effected. Local anaphylaxis was proposed as a possible means of parasite clearance; this hypothesis has been supported by the demonstration of specific reaginic antibody production[3] and jejunal mast cell accumulation[4] in infected animals. In addition, increased mucus secretion[5] and more recently, goblet cell proliferation in the jejunal mucosa of rats[6] have been noted and considered as potentially important in mediating the self-cure reaction. The data presented below indicate that in the absence of demonstrable mast cells, the course of a primary infection with this parasite is unchanged; however, they are supportive of a role for goblet cells in the self-cure reaction.

We have taken advantage of the availability of mast cell-deficient mice to examine the relative contribution of mast cells and goblet cells to the expulsion of *N. brasiliensis*. Either of two mutant alleles at the dominant-spotting locus of the mouse genome, *W* or W^v, when homozygous, is associated with a defect in a pluripotential stem cell precursor[7]. The hybrid W/W^v mouse, resulting from a cross between WB/Re-*W*/+ and C57Bl/6-W^v/+ parents, is grossly deficient of tissue mast cells, as documented by Kitamura *et al.*[7]. The immunological status of these mice with respect to thymus-derived and bone marrow-derived lymphocytes, however, seems to be normal[8]. W/W^v mice, their sex-matched littermates without the mutant alleles (+/+ mice) and C57Bl/6 mice (a background strain), were used in this study.

Kitamura *et al.*[7] demonstrated the mast-cell deficiency of W/W^v mice in histological studies of toluidine blue-stained sections of numerous tissues, including skin and gastrointestinal tract. We confirmed their findings, and obtained the following additional functional and biochemical evidence. First, we found no mast cells in the jejunal mucosa of W/W^v mice. Mast cells were quantitated histologically by removing the entire small intestine and fixing immediately in Carnoy's solution. Sections 2 cm in length were taken from the jejunum and dehydrated in an ascending ethanol series and cleared in α-terpineol. They were then embedded in paraffin and 8-μm sections were cut with a standard microtome. Slides were prepared and stained with astrablau- safranin to demonstrate mast cells[9]. In examining a total of 800 villus-crypt units (VCU) from four W/W^v mice, no mast cells were found. In contrast, there was an average of 0.7 ± 0.13 mast cells per 10 VCU in each of four +/+ controls. This number was somewhat less than that reported in mice of other strains; for example, Swiss–Webster mice may have 25 mast cells/10 VCU (ref. 10). Next, the absence of a passive cutaneous anaphylactic reaction in five 8-week-old male W/W^v mice, tested in the same way as three +/+ controls who were consistently reactive recipients in this assay, provided functional evidence for the mast cell deficiency in their skin. Finally, peritoneal cells from W/W^v mice were shown to lack mast cells, as well as histamine, a biochemical marker for mast cells. Thus, a 20-μl aliquot of an aspirated peritoneal cell suspension from each of five W/W^v mice was consistently negative for histamine using a radioenzymatic technique[11], while a similar aliquot taken from each of three +/+ controls contained an average of 3.6±0.8 ng histamine. (The lower limit of detection of histamine by this method is 0.1 ng per 20 μl.) Examination of samples of the aspirated cells, stained according to Mota's technique[12], confirmed that equal numbers of cells were present in all of the suspensions assayed, although mast cells comprised 11.2±3.6% of the cells from +/+ mice whereas no mast cells were detected among the cells obtained from W/W^v mice. Observations of the profound mast cell deficiency in the W/W^v mouse are thus supported and extended.

In normal mice, infection with *N. brasiliensis* is associated with a marked (at least tenfold) increase in mast cells in the jejunal mucosa[10]. Not surprisingly, this was not the case in W/W^v mice. After infection by the subcutaneous injection of 500 third-stage larvae of *N. brasiliensis*, no mast cells appeared in the jejunum of W/W^v mice up to day 21 after infection, whereas mast cells numbers did increase in +/+ mice (Fig. 1). Of 24 W/W^v and 24 +/+ mice, equal numbers of randomly selected animals were killed immediately before and on days 7, 10, 14, 17 and 21 post-infection, and their intestines prepared as described above. It was not until after day 7 post-infection that the number of mast cells began to increase in mice of the +/+ genotype. Mast cell accumulation continued up to day 21 in this control group.

The course of worm infection, however, determined by killing mice and counting the number of adult worms in the small intestine, was found to be parallel in W/W^v and control mice (Table 1). The course in all three groups of mice was similar to that reported with C3H mice[2]. On day 7, adult worms were found predominantly in the first third of the intestine (measured from the pyloric sphincter) in each group of mice. On day 14, no worms were found in any mouse except one, a C57Bl/6 mouse, which had retained a single worm.

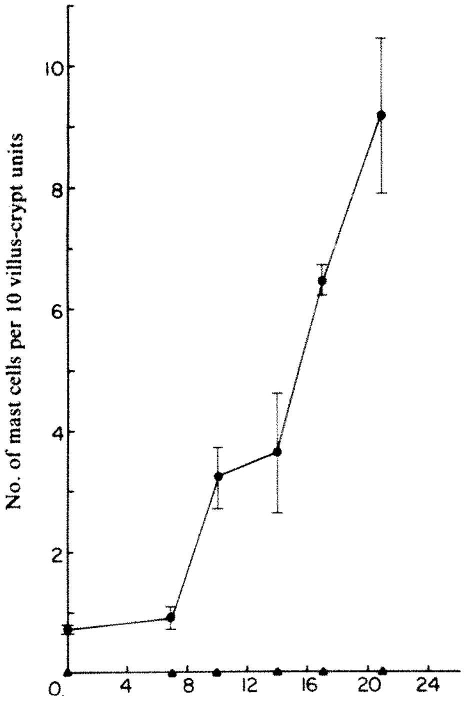

Fig. 1 Intestinal mast cell counts of W/W^v (▲) and +/+ (●) mice during the course of primary infection with *N. brasiliensis*. Twenty-four mice of each genotype were infected on day 0, each with 500 infective third-stage larvae; four of each group were sacrificed on each of the indicated days. A minimum of two sections from each mouse was examined at 400× magnification to identify and count mast cells in the villus-crypt units (VCU). At least 40 VCU in each tissue sample were examined; in sections from W/W^v mice, at least 100 VCU were examined. Standard errors are indicated by vertical bars.

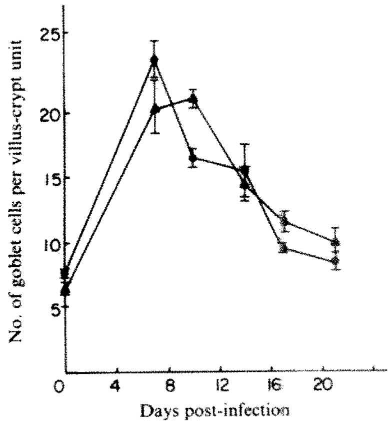

Fig. 2 Intestinal goblet cell counts of W/W^v (▲) and +/+ (●) mice during the course of a primary infection with *N. brasiliensis*. Sections contiguous with those stained for mast cells (refer to Fig. 1) were stained with alcian blue-periodic acid Schiff's[6] and examined for goblet cells (400×). At least 40 VCU in each tissue sample were examined. Standard errors are indicated by vertical bars.

At the same time, increases in goblet cell numbers were apparent in both groups of infected mice, as seen in Fig. 2. Before infection, W/W^v mice appeared to have fewer goblet cells than +/+ mice. On day 7 post-infection, there was a 2–4-fold increase in the number of goblet cells in the jejunal epithelium in both groups of mice. By day 10, the number of goblet cells had already begun to decline, approaching the pre-infection level by day 21. These observations are supported by the appearance of increased mucus content in the jejunum in the regions containing the most worms, particularly evident on day 7. It is noteworthy that intestinal goblet cell numbers and mucus secretion during the course of *N. brasiliensis* infection in these animals more closely paralleled the intestinal worm burden than did the number of intestinal mast cells. These observations are comparable to those made in rats infected with the same parasite[4,6].

Mast cell infiltration of the intestinal mucosa in the presence of specific IgE antibodies has long been taken to suggest that a local anaphylactic-like mechanism is involved in the expulsion of *N. brasiliensis* from the rodent intestine. Nevertheless, involvement of these cells has been questioned[13]. As demonstrated in the present experiment, expulsion in the absence of intestinal mast cells is strong evidence that mast cells and an anaphylactic-like reaction are not necessary for the effective clearance of intestinal worms after a primary infection. Furthermore, the maximum accumulation of intestinal mast cells in normal mice and rats occurs post-infection, which suggests that these cells may have some other role in this process. For example, they may serve a regulatory function[14].

The hypothesis that intestinal goblet cells play a part in the host response to helminthic parasites, suggested as early as

Table 1 Worm burden found in the small intestines of mice of different genotypes on days 7 and 14 post-infection

	Mean worm burden	
Genotype	Day 7	Day 14

Groups of eight W/W^v, eight +/+ and eight C57Bl/6 mice were infected by the injection of 500 third-stage larvae. Four per group were killed on the indicated days; the small intestine was removed and plac in saline solution. Under direct microscopic observation (10× intestine was opened longitudinally in 1 cm segments and [illegible]70). worms identified and counted. Values are means ±s.e.m.

* Differences on day 7 are not statistically significa

1939[15], was later invoked in *N. brasiliensis* infections[5] and is reinforced by the current data. The apparent increase in the secretion of mucus, much of which might be due to the increased numbers of goblet cells, could provide a means for the mechanical expulsion of the worms as well as being a vehicle for the delivery of host antibody and cells to the site of parasite attachment. The roles of goblet cells, mast cells and their products in immunity to helminths is deserving of further investigation.

We thank Dr Saul Sharkis for supplying W/W^v and $+/+$ mice, and Steven Guarnaccia for technical assistance. This work is supported by grants from the US PHS (AI 07057 and AI 14480).

Haematopoietic growth factors are released in cultures of H-2-restricted helper T cells, accessory cells and specific antigen

M. H. Schreier & N. N. Iscove

Basel Institute for Immunology, Postfach CH 4005 Basel, Switzerland

Colony formation by mammalian haematopoietic cells in culture depends on specific glycoprotein growth factors. 'Colony-stimulating factors' for granulocytic[1,2] and macrophage[3,4] precursors (G- and M-CSFs), as well as for pluripotential and early committed erythroid cells ('burst promoting activity, or BPA[5]) are released in cultures of stimulated spleen, lymph node or peripheral blood cells[5–8]. In such systems the induction stimulus has been either allogeneic cell antigens, or lectins which stimulate T cells, such as pokeweed mitogen, concanavalin A (Con A) or phytohaemagglutin[6] and both T cells and adherent cells are implicated in the process[7,8]. The complexity of the spleen cell populations used in earlier *in vitro* studies has made it difficult to establish the cellular source of the factors and the mechanisms leading to their release. Pure populations of continuously growing cell lines of either monocytic/macrophage[1] or T-cell[10,11] character have already been shown to release haematopoietic activities constitutively. However, such evidence cannot prove that these functions are also expressed by the normal counterparts of these lines. We have reduced the complexity of the spleen cell system by supplying helper T cells in the form of pure clonal populations of known physiological function and antigenic specificity, and demonstrate here that activity is released when helper T cells are cultured with specific antigen, and that release depends on H-2 (I-A region) restricted interaction with accessory cells present in spleen or normal peritoneal cavity.

Table 1 indicates that activities stimulating granulocytic, macrophage and large erythroid colonies are released during in[illegible]dary immune responses by mouse spleen cells in culture. In [illegible]periment, C57BL/6J mice were immunized [illegible] with 10^7 sheep or horse red blood cells. After 3 weeks, spleen cells were cultured in serum-free medium with or without added antigen. Immunological reactivity was monitored by enumerating antibody-producing (plaque-forming) cells (PFC) specific for the challenging antigens after 5 days of culture. The supernatant culture medium was collected after 5 days and assayed for growth-promoting activity in methylcellulose cultures of mouse bone marrow. In these culture conditions, unstimulated spleen cells spontaneously released a background level of activity. However, factor release rose above this background when the cultures contained antigen, correlating positively with the immune responses indicated by PFC. Factor release was most marked when the cells were challenged in culture with the same antigen to which they had been immunized *in vivo*. As also indicated in Table 1, when the spleen cells were treated with an anti-Thy-1 antiserum plus complement before incubation with antigen, no induction of activity above background occurred.

Such experiments documented that recognition of antigen by normal T cells could result in release of haematopoietic factors. However, interpretation of data from this system is complicated by the complexity of the spleen cell population, and the high background levels of factor release even in the absence of homologous antigen. For this reason, we turned to a system in which the functional T-cell component was represented by pure cloned antigen-specific helper T cells. Such cells were derived from immunized spleen cells selectively enriched in culture by repeated antigenic stimulation and finally cloned out in the presence of T-cell growth factor (IL-2)[12–14]. As seen in Table 2, significant haematopoietic factor activity was released in cultures of T-helper-cell clones, but only when both appropriate antigen and syngeneic 'accessory cells' were also present. The latter were provided either by spleen cells (10^6 ml^{-1}) from nude mice devoid of functioning T-helper cells, or more efficiently on a per cell basis by resident peritoneal cells (5×10^4 ml^{-1}).

Function of helper T cells in immune responses is known to involve cellular interactions. These include recognition of major histocompatibility antigens on B cells and 'accessory' cells[15] by the T cells. In the mouse, these antigens are the I–A antigens of the H–2 complex. We accordingly investigated whether the induction of haematopoietic factors in this system would also be H–2 'restricted'. Pure cloned antigen-specific helper T cells were cultured with appropriate antigen, and with accessory cells from congeneic mouse strains recombinant at various points in the H–2 region. The accessory cells were supplied in the form of irradiated spleen cells from which mature T cells had been eliminated by treatment with anti-Thy-1 antiserum and complement. The results, also shown in Table 2, indicate that induction of factor release depends on identity of genotype between the T-helper cell donor and the accessory cells to the left of the I–B subregion of H–2. In a control experiment of the type shown in Table 1, the negative accessory cell donors (B10A.4R and B10A) were comparable to C57BL/6J in their capacity to release CSFs and BPA in response to antigen. Appropriate congeneic strains were not available at the time of these experiments for distinguishing between K- or I–A-region restriction. However, the action of T-helper cells in immune responses *in vivo* has been demonstrated to involve restriction only at I–A[15].

Our experiments indicate that haematopoietic factors are released during immune responses to red cell antigens in culture. The experiment in Table 1 documented such release with normal freshly explanted spleen cell populations. Experiments using pure clonal helper T-cell populations reproduced this phenomenon, providing an additional point of resemblance in function between these clones and their normal counterparts in spleen. In addition, the experiments showed that such release requires both recognition of the antigen by antigen-specific helper T cells, and an interaction, restricted most probably at I–A, between these T cells and Thy-1-negative accessory cells present in spleen or peritoneal cavity. Factors stimulating T (ref. 14) and B (ref. 16) cell growth have already been shown to be released in the same system with similar requirements.

Cultures (0.2 ml) contained 3 × 10^3 helper T cells (C57BL/6J), accessory cells and 5 × 10^5 red cells where indicated. Serum-free medium and incubation as in legend to Table 1, except that cultures were not rocked. Supernatant medium was collected after 5 d of culture and assayed in methylcellulose cultures of 7 × 10^4 bone marrow cells ml^{-1} as in Table 1. Colony counts, pooled from two independent assays, are expressed as per cent of the counts (MΦ, 200; G, 12; E, 45 per 10^5 marrow cells) in the first experimental group (HRC, *nu/nu* spleen, HRC).

* 2 × 10^5 per culture.

† 1 × 10^4 per culture.

‡ Congeneic spleen cells were irradiated (3,000 rads) and treated with α-Thy-1 serum plus complement before addition (2 × 10^5 cultures.

While it is easy to understand the usefulness of production of lymphopoietic factors under these circumstances, and perhaps of activities stimulating monocyte/macrophage and granulocyte production, the significance of BPA production is less obvious. Perhaps it serves to increase the supply of early committed myeloid and lymphoid precursors[5]. There is an indication that T cells may play a role in stimulating haemopoietic cell growth in the whole animal: Thy-1-bearing cells appear to be required for successful growth of haemopoietic cell grafts in genetically defective W/W^v mice[9]. Since the T-cell deficient nude mouse does not show any gross defect in haematopoiesis, we would suggest that antigen recognition is unlikely to represent the only available pathway to haematopoietic factor production. Perhaps both immunological and non-immunological signals impinge on a cellular system present in the accessory cell population and able to release factors in response to either signal. The presence of a functioning accessory cell population in *nu/nu* spleen is documented in Table 2. The view would predict that haematopoiesis in *nu/nu* mice will prove defective in relation to their normal counterparts only when comparisons are performed during immune reactions.

The experimental system described here, which makes use of pure cloned helper T cells in combination with T-cell-depleted accessory cell populations, provides a basis for specific assay both of the accessory cells and of the signals exchanged between them and helper T cells. Because the culture system contained a source of accessory cells in addition to the helper lymphocyte clones, it is not possible to draw conclusions about the cellular source of the haematopoietic factors from our results. It therefore remains for future experiments to determine the identity of the accessory cells, the cellular source of the factors, and the nature of the I–A-restricted interaction.

We thank R. Tees and M. Schweizer for technical assistance.

Regulation by angiotensin II of its receptors in resistance blood vessels

Stephen Gunther, Michael A. Gimbrone Jr & R. Wayne Alexander

Departments of Medicine and Pathology, Peter Bent Brigham Hospital and Harvard Medical School, Boston, Massachusetts 02115

The sensitivity of blood vessels to the vasoconstrictor effects of the hormone angiotensin II appears to be modulated by the activity of the renin–angiotensin system. Elevation of circulating angiotensin II levels by sodium depletion or renal artery stenosis is associated with a diminished pressor response to infused angiotensin II (refs 1–3). Conversely, the vasoconstrictor response to the hormone is enhanced when endogenous angiotensin II levels are reduced by sodium loading[1,4] or nephrectomy[5]. The mechanisms of these varying effects are not known, but physiological and pharmacological experiments suggest involvement of the vascular smooth muscle receptor for angiotensin II (refs 5–8). Modification of the interaction between angiotensin II and its vascular receptor, resulting in altered responsiveness to the hormone, could occur either via 'prior occupancy' of receptors by elevated levels of endogenous angiotensin II resulting in fewer free receptors available to respond to circulating angiotensin II (ref. 5), or, elevated levels of angiotensin II could result in a decrease in receptor affinity for the hormone[7] or a decrease in total receptor number in the vascular smooth muscle cell[8]. We now report the first direct evidence, by radioligand binding assay, that angiotensin II regulates the number of its own receptors in resistance vasculature.

We have recently characterized, in a particulate fraction from rat mesenteric arteries, ^{125}I-angiotensin II binding sites which have the high affinity (equilibrium dissociation constant, K_d = 9.1 nM), low capacity (54 fmol per mg protein), and specificity ed of the physiological angiotensin II receptor[9]. In the dy we have used this system to characterize the vascular angiotensin II receptor in rats in which circulating angiotensin II levels were normal, chronically elevated in response to sodium depletion[10], or depressed by inhibition of angiotensin I converting enzyme[11].

Male Sprague–Dawley rats (300–325 g) were obtained from Charles River Breeding Labs. Control rats ($n = 160$) were maintained on a normal sodium diet (0.29% Na; Ralston Purina) and tap water. Sodium-depleted rats ($n = 160$) were fed a low-sodium diet (<0.05% Na; Hartroft Formula, ICN Life Sciences Group) and distilled water for one to three weeks. A third group of rats ($n = 40$) was also fed the low-sodium diet and distilled water for three weeks, but during the final three days of the diet, the angiotensin converting enzyme inhibitor SQ-14,225 (2-D-methyl-3-mercaptopropanoyl-L-proline; Squibb), 100 mg kg^{-1} day^{-1}, was added to the drinking water. At weekly intervals, 40 control and 40 sodium-depleted rats were killed and plasma renin activity[12] and ^{125}I-angiotensin II binding to mesenteric artery particulate fractions determined as previously described[9]. Similar assays were performed in the sodium-depleted, SQ-14,225-treated rats following the third day of drug administration. Mesenteric artery ^{125}I-angiotensin II binding site capacity and affinity were estimated by Scatchard analysis of binding data. Statistical significance was determined by unpaired, 2-tailed *t*-test, comparing the results of each treated group with those of the simultaneous controls.

In control rats, plasma renin activity averaged 3.1 ± 0.3 (s.e.m.) ng ml^{-1} h^{-1}, and mesenteric artery particulate fractions contained 56.9 ± 1.2 fmol per mg protein of angiotensin II receptors. Neither plasma renin activity nor angiotensin II receptor density varied significantly during the three weeks on the normal sodium diet. In rats maintained on the low-sodium diet alone, plasma renin activity was increased significantly at one week, and by three weeks had reached 5.2 ± 0.5 ng ml^{-1} h^{-1} ($P < 0.05$ compared to control, see Fig. 1). This activation of the renin–angiotensin II system was associated with a significant decrease in ^{125}I-angiotensin II binding capacity in mesenteric artery particulate fractions ($P < 0.01$ compared to control, weeks 1–3; see Fig. 1). After three weeks of sodium depletion, ^{125}I-angiotensin II binding capacity was reduced to 76% of control (41.5 ± 3.3 vs 54.3 ± 3.8 fmol mg^{-1}). In the rats given the

0028-0836/80/38023 1.00

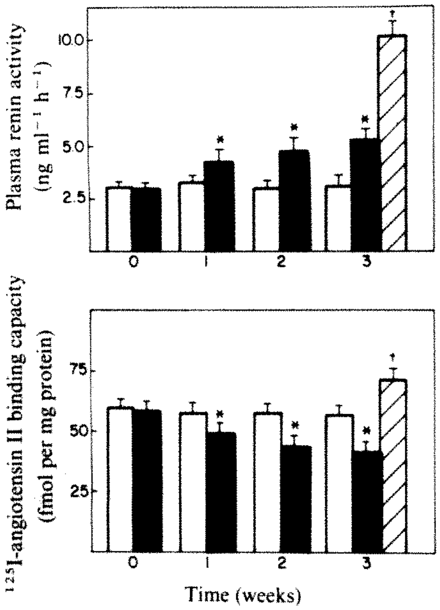

Fig. 1 Changes in plasma renin activity (upper panel) and ^{125}I-angiotensin II binding capacity of mesenteric artery particulate fractions (lower panel) at weekly intervals in rats fed a normal sodium diet (open bars), a sodium-deficient diet alone (solid bars), and a sodium-deficient diet plus 3 days of converting enzyme inhibitor SQ-14,225 (striped bars). Values represent mean ± s.e.m. of four experiments. For each experiment, ten control and ten treated rats were decapitated 15 min after the intraperitoneal administration of heparin, 100 U, and blood collected into iced Vacutainer® tubes containing EDTA for measurement of plasma renin activity[12]. Particulate fractions from mesenteric artery homogenates were prepared from the same animals, as previously described[9]. ^{125}I-angiotensin II binding was determined by incubating aliquots of the particulate fraction (80–100 μg protein) with 0.1–2.0 nM concentrations of ^{125}I-angiotensin II (specific activity 900–1,400 Ci mmol^{-1}) in 0.20 ml assay buffer (50 mM Tris, 5 mM $MgCl_2$, 0.25% bovine serum albumin, *p*H 7.2). After steady-state binding was achieved (90 min at 22 °C), bound and free radioactivity were separated by rapid filtration through Whatman GF/C filters and trapped radioactivity counted in a well-type gamma counter (Searle). Specific binding, defined as (total binding) − (binding in the presence of 1 μM unlabelled angiotensin II), averaged 90% of total counts bound. * = $P < 0.05$ compared to simultaneous controls (normal diet). † = $P < 0.01$ compared to both control and sodium-deficient diet groups.

converting enzyme inhibitor SQ-14,225, during the final three days of the three-week sodium-deficient diet, plasma renin activity was significantly higher, 10.1 ± 0.6 ng ml^{-1} h^{-1} ($P < 0.01$ compared to third week levels in both control rats and rats sodium depleted only). The inhibition of angiotensin II formation in this group of rats, however, resulted in a significant increase in mesenteric artery ^{125}I-angiotensin II binding capacity, to 69.0 ± 4.3 fmol mg^{-1} (an increase of 66% compared to the third week levels in rats sodium depleted only, $P < 0.01$, and of 27% compared to control rats, $P < 0.01$). The changes in ^{125}I-angiotensin II binding capacity produced by sodium depletion or converting enzyme inhibition were not accompanied by a significant change in receptor affinity (Fig. 2).

Our results suggest that the number of angiotensin II receptors in rat mesenteric arteries responds to circulating angiotensin II levels. Increased levels of hormone induced by sodium depletion resulted in a significant decrease in receptor number, whereas inhibition of angiotensin II formation by SQ-14,225 had the opposite effect. That the observed changes in receptor number correlated directly with variations in circulating angiotensin II levels is supported by the following facts: (1) ^{125}I-angiotensin II binding to mesenteric artery particulate fractions is independent of sodium and potassium concentrations from 0 to 100 mM (ref. 9); changes in intra- or extracellular electrolyte composition during sodium deprivation therefore could not affect the binding assay used; (2) ^{125}I-angiotensin II binding is likewise unaffected by bradykinin concentrations as high as 10^{-5} M (ref. 9); the increase in binding capacity following SQ-14,225 administration thus cannot be attributed to an accumulation of endogenous bradykinin resulting from SQ-14,225 inhibition of vascular kininase II activity[13]; (3) renin itself does not appear to play a role, as the increase in plasma renin activity in sodium-depleted rats was associated with a decrease in receptor number, while an even greater increase in plasma renin activity in rats sodium depleted and given SQ-14,225 (due to loss of feedback inhibition of renin release by endogenous angiotensin II (ref. 11)) was accompanied by an increase in receptor number; and finally, (4) an artefactual change in apparent receptor binding capacity due to diet-induced changes in cellular membranes is excluded because both groups of treated rats were maintained on the same low-sodium diet, yet had opposite changes in ^{125}I-angiotensin II binding capacity.

A potential explanation for the results observed in these studies is that receptor-associated endogenous angiotensin II carried over into the *in vitro* binding assay could account for the decrease in binding capacity observed with sodium depletion. To provide insight into this possiblity, we perfused the mesenteric arteries of control rats *in situ* for 15 min with supraphysiological (2 nM) concentrations of ^{3}H-angiotensin II, a radioligand possessing the full biological activity of the native hormone[14], and followed the amount of radioactivity remaining associated with the tissue during the usual preparation of the particulate fraction. As shown in Table 1, immediately following *in situ* perfusion, 68.4 fmol of mesenteric artery receptors were occupied by ^{3}H-angiotensin II, yet less than 2% of the total radioactivity initially present, and essentially none of that which was specifically associated with receptors, was still detectable in

Table 1 *In vivo* labelling of mesenteric artery angiotensin II receptors by perfusion with ^{3}H-angiotensin II

	Crude homogenate		Particulate fraction		
Perfusate	Total radio-activity* (d.p.m.)	^{3}H-angio-tensin II (fmol)	Total radio-activity (d.p.m.)	^{3}H-angio-tensin II (fmol)	Total protein content (mg)
^{3}H-angiotensin II	14,600	257.0	122	2.1	1.44
^{3}H-angiotensin II + antagonist	10,710	188.6	194	3.4	1.40
(Difference)	(3,890)	(68.4)	(0)	(0)	

The mesenteric arteries of three ether-anaesthetized rats (normal diet) were perfused *in situ* at a rate of 0.38 ml min^{-1} with Krebs–Ringer phosphate buffer (*p*H 7.4) for 30 min at 38 °C. During the final 15 min of perfusion, ^{3}H-angiotensin II (specific activity 25.6 Ci mmol^{-1}; NEN) was added to the perfusate at a final concentration of 2 nM. At the end of the perfusion period, the mesenteric arteries from all three rats were excised and washed in ice-cold phosphate-buffered saline (*p*H 7.4). The combined vessels then were homogenized in 10.0 ml ice-cold 0.25 M sucrose as described in ref. 9. An aliquot of this homogenate (1.0 ml) was counted in a liquid scintillation counter (Beckman) to determine the total amount of radioactivity initially present in the vessels from the three rats ('crude homogenate'); the remaining 9.0 ml of the homogenate were then used to prepare a particulate fraction in the same manner as for the radioligand binding assay. The resultant particulate fraction from the three rats (104,000*g* pellet) was resuspended in 0.5 ml water; duplicate 50-μl aliquots were taken to measure total protein content (Lowry method) and the remaining 0.4 ml were counted as above to determine the amount of radioactivity still present in the purified particulate fraction. To determine what fraction of the radioactivity observed at each of these steps represented ^{3}H-angiotensin II specifically associated with receptor, identical experiments were repeated in three additional rats including the angiotensin II antagonist (Sar_1, Ile_8)-angiotensin II (1 μM) in the perfusate for the entire 30-min perfusion period ('^{3}H-angiotensin II + antagonist'). As this dose of the competitive antagonist is sufficient to block the binding of 2 nM angiotensin II to vascular receptors completely[9,15], the radioactivity present in the tissue from these animals presumably reflects ^{3}H-angiotensin II nonspecifically bound or trapped in extracellular fluid. The difference in the amounts of ^{3}H-angiotensin II present in the crude homogenates of the two groups (68.4 fmol) therefore represents ^{3}H-angiotensin II specifically bound to receptors. On the basis of an average ^{125}I-angiotensin II binding capacity of 56.9 fmol per mg protein in the particulate fraction from control animals (Fig. 1), and the total protein contents of the particulate fractions in this experiment (1.40–1.44 mg), the most conservative estimate of the total number of angiotensin II receptors in each of the cr homogenates is ≈81 fmol. Thus, the observed value of 68.4 fmol ^{3}H-angio specifically bound is not excessive. *None of this specifically bound* ^{3}H- II was detected in the final particulate fraction.

* Corrected for counter efficiency and quenching.

the final particulate fraction. Thus, in the experimental conditions of this study, any angiotensin II bound to receptor, after relatively brief exposure *in vivo*, seems to be readily dissociable. Endogenous angiotensin II bound in this state therefore could not account for the observed changes in binding capacity.

The apparent inverse relationship between ambient hormone concentration and angiotensin II receptor density in vascular smooth muscle is similar to that observed with other peptide hormones, such as insulin[16], glucagon[17] and growth hormone[18]. In contrast, angiotensin II seems to regulate its receptors in the adrenal gland in a different manner[19]. In this tissue, angiotensin II-stimulated aldosterone production is potentiated when circulating levels of angiotensin II are chronically elevated, as during sodium depletion[20,21]; *in vitro* binding studies have shown that this increased sensitivity is accompanied by an increase in adrenal angiotensin II receptors[21,22]. Although the regulation by endogenous angiotensin II concentrations of end-organ responsiveness of adrenal and vascular tissues to angiotensin II is directionally opposite, both effects appear to be mediated, at least in part, by hormone-induced changes in receptor number.

Previous direct studies of the regulation of angiotensin II receptors in smooth muscle have used uterine membrane fractions. These studies have yielded conflicting results. Bilateral nephrectomy has been shown to increase both the contractile response of uterine smooth muscle to angiotensin II (ref. 23) and the angiotensin II binding capacity of uterine membranes[24]. The effects of sodium depletion on uterine smooth muscle, however, are contradictory. While Aguilera *et al.*[21] found that sodium depletion for seven days in rats decreased uterine angiotensin II-binding capacity by 40%, Devynck *et al.*[22] reported that sodium depletion for four weeks resulted in an increase in binding capacity. Although the reasons for this discrepancy are not clear, the difficulties in extrapolating binding data from the uterus, a tissue which does not respond to physiological concentrations of angiotensin II, to vascular smooth muscle have been discussed[22].

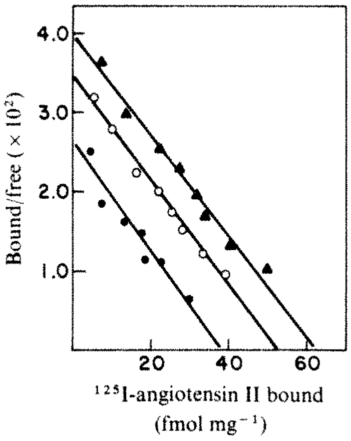

Fig. 2 Representative Scatchard plots of ^{125}I-angiotensin II binding to mesenteric artery particulate fractions from control rats (○), rats sodium depleted for 3 weeks (●), and from sodium-depleted rats given SQ-14,225 (▲). Particulate fractions from ten rats were used in each experiment. Mean equilibrium dissociation constants (K_d) for control (1.04 ± 0.19 nM), sodium-depleted (0.79 ± 0.07 nM), and SQ-14,225-treated (0.94 ± 0.12 nM) groups were not significantly different.

The changes in vascular angiotensin II receptors directly demonstrated in this study, during chronic sodium depletion and converting enzyme inhibition, are consistent with the hypothesis that receptor regulation can modulate vascular responsiveness angiotensin II. At the cellular level several possible sms could contribute to these hormone-induced alter- ptor number. As the *in vivo* receptor labelling experiment indicates, readily reversible binding of hormone to its receptor, *per se*, should not directly influence binding capacity. However, association of hormone with a high-affinity, slowly reversible state of its receptor could result in a transient decrease in binding capacity, through reduction in the number of available receptors. This form of receptor occupancy, if accompanied by uncoupling from secondary biochemical events, might lead to diminished physiological responsiveness. Alternatively, fluctuations in ambient hormone concentration might influence the rates of receptor degradation and/or synthesis, thus changing total receptor number. The relative contributions of these two mechanisms cannot be determined by current techniques *in vivo*. However, preliminary data from our laboratory, in cultured vascular smooth muscle cells suggests that both processes may be involved in regulating the number of angiotensin II receptors available for interaction with hormone. Exposure of cultured rat mesenteric artery smooth muscle cells to 3×10^{-8} M angiotensin II for up to 6 h results in a time-dependent decrease in ^{125}I-angiotensin II binding capacity. The decrease in binding capacity resulting from brief exposure (5 min) is completely reversible within 30 min after removal of angiotensin II from the medium. With longer periods of exposure to angiotensin II (up to 6 h), ^{125}I-angiotensin II binding capacity decreases progressively and recovery requires 4–5 h. Unlike the recovery after short angiotensin II exposure, complete recovery of binding capacity after 6 h of angiotensin II exposure requires new protein synthesis, implying that receptor degradation has occurred. Thus, readily reversible alterations of the angiotensin II receptor may contribute to the relatively rapid changes in vascular responsiveness seen *in vivo* during acute manipulations of the renin–angiotensin system[25,26]. On the other hand, chronic changes in the activity of the renin–angiotensin system may be associated with changes in the kinetics of receptor turnover in vascular smooth muscle cells. These forms of hormone-induced receptor regulation may be important determinants of vascular responsiveness to the vasoconstrictor effects of angiotensin II.

SQ-14,225 was kindly provided by Dr Z. P. Horovitz. We thank Dr Gordon Williams for the measurements of renin activity and Ms Rae Caravaty for technical assistance. Regulation of non-muscle myosin assembly by calmodulin-dependent light chain kinase

J. M. Scholey, K. A. Taylor* & J. Kendrick-Jones

MRC Laboratory of Molecular Biology, Hills Road,
Cambridge CB2 2QH, UK

The presence of actin and myosin in non-muscle cells suggests that they may be involved in a wide range of cellular contractile activities[1]. The generally accepted view[2] is that interaction between actin and myosin in these cells[3-5] and in vertebrate smooth muscle[6,7], is regulated by the level of phosphorylation of the 20,000-molecular weight (MW) light chain. In the absence of calcium, this light chain is not phosphorylated and the myosin cannot interact with actin. Calcium activates a specific calmodulin-dependent kinase[8-11] which phosphorylates the light chain, initiating actin–myosin interaction. Although most studies on the role of phosphorylation have concentrated on the regulation of actin-activated myosin Mg-ATPase activity, phosphorylation of the light chain also seems to control the assembly of smooth muscle myosin into filaments[12,13]. Using purified smooth muscle light chain kinase, we have confirmed this observation. We report here studies of myosins isolated from the two non-muscle sources, thymus cells and platelets. We observed that these myosins are assembled into filaments at physiological ionic strength and Mg-ATP concentrations, only when the 20,000-MW light chain is phosphorylated.

We initially compared the stability of myosin filaments prepared from non-phosphorylated calf thymus myosin and rabbit skeletal myosin as a function of the Mg-ATP concentration (Fig. 1). The turbidity measurements and electron micrographs show that the filaments from thymus myosin (bipolar filaments, average length 3,380 ± 560 Å) are disassembled completely at a molar ratio of less than 5 mol Mg-ATP per mol myosin, suggesting that Mg-ATP acts at an approximately stoichiometric ratio. Similar results were obtained with myosins isolated from pig platelets and chicken gizzard muscles. These results differ from those of earlier work[14] which indicated that myosin isolated from human platelets formed short bipolar filaments which were stable in a wide range of conditions, including the presence or absence of Mg-ATP at physiological ionic strength.

Filaments prepared from phosphorylated thymus or gizzard myosins were stable at millimolar concentrations of Mg-ATP. Similarly, thymus and gizzard myosin rod subfragments (the tail fragment which contains the self-assembly properties of the myosin) formed filaments which were not disassembled at the Mg-ATP concentrations used in these experiments (up to 10 mM). Mg-pyrophosphate would not substitute for Mg-ATP in disassembling non-phosphorylated thymus or gizzard myosin filaments. These observations suggest that Mg-ATP acts at a specific high-affinity binding site in the subfragment-1 (myosin head) portion of the molecule, which may be the Mg-ATPase active site.

Myosins isolated from rabbit and scallop striated muscles form filaments which are stable at millimolar concentrations of Mg-ATP. In this case, the lack of effect of Mg-ATP must be due to differences in the subunits of these myosins compared with those of vertebrate smooth muscle and non-muscle myosins. These experiments were carried out in conditions roughly comparable to those that are expected to exist inside a 'resting' cell, namely 0.15 M KCl, 1 mM Mg-ATP and the absence of Ca^{2+}. We therefore predict that '*in vivo*', the myosin in resting

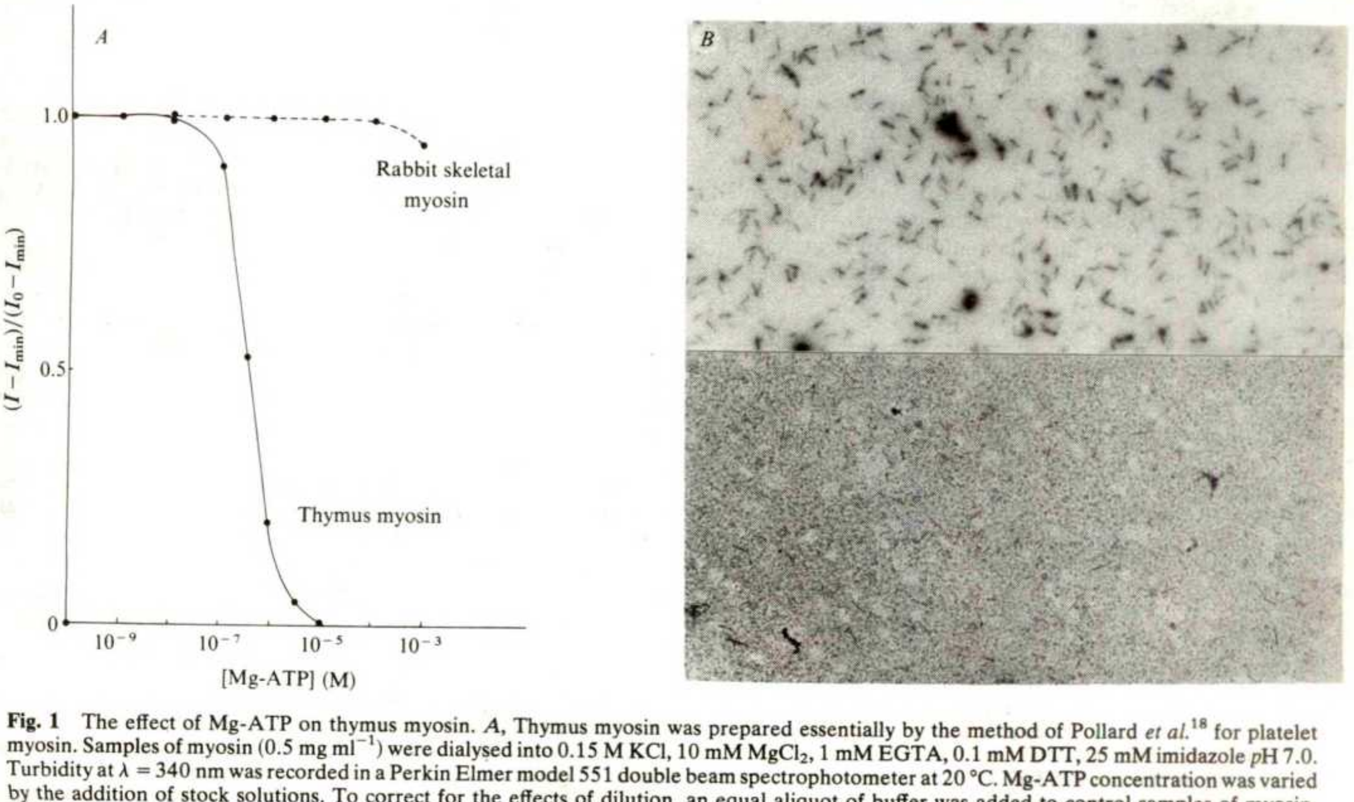

Fig. 1 The effect of Mg-ATP on thymus myosin. *A*, Thymus myosin was prepared essentially by the method of Pollard *et al.*[18] for platelet myosin. Samples of myosin (0.5 mg ml^{-1}) were dialysed into 0.15 M KCl, 10 mM $MgCl_2$, 1 mM EGTA, 0.1 mM DTT, 25 mM imidazole *p*H 7.0. Turbidity at $\lambda = 340$ nm was recorded in a Perkin Elmer model 551 double beam spectrophotometer at 20 °C. Mg-ATP concentration was varied by the addition of stock solutions. To correct for the effects of dilution, an equal aliquot of buffer was added to control samples of myosin. Background turbidity was corrected by plotting $(I - I_{min})/(I_0 - I_{min})$. I is turbidity measured at 340 nm, I_0 the turbidity in the absence of Mg-ATP, and I_{min} the minimal level of turbidity attained during the experiment. Typical values are $I_0 = 0.4$ and $I_{min} = 0.15$. It must be stressed that turbidity measurements should always be used in conjunction with electron microscope observations so as to 'estimate' the degree of filament assembly–disassembly. *B*, Electron micrographs of thymus myosin before (top) and after (bottom) addition of 50 μM Mg-AT
Specimens were prepared by placing 10 μl of the myosin solution to be examined on to carbon-coated 400-mesh grids, allowing the drop to
for exactly 30 s, then washing with 13 drops of buffer (−ATP) and 10 drops of 1% uranyl acetate. Micrographs were examined on
EM400 operated at 80 kV. ×5,000.

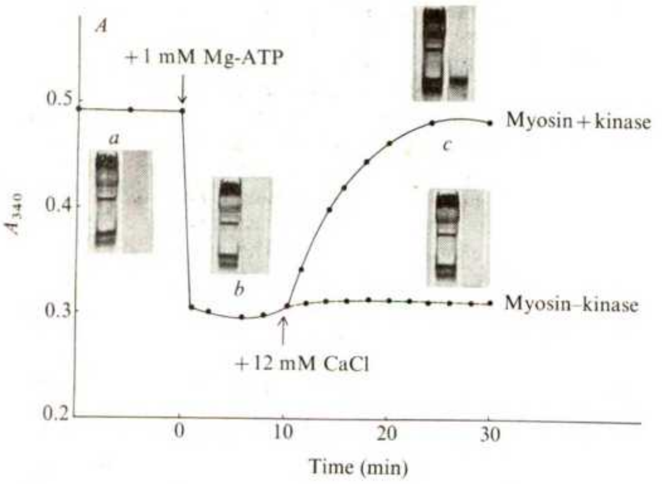

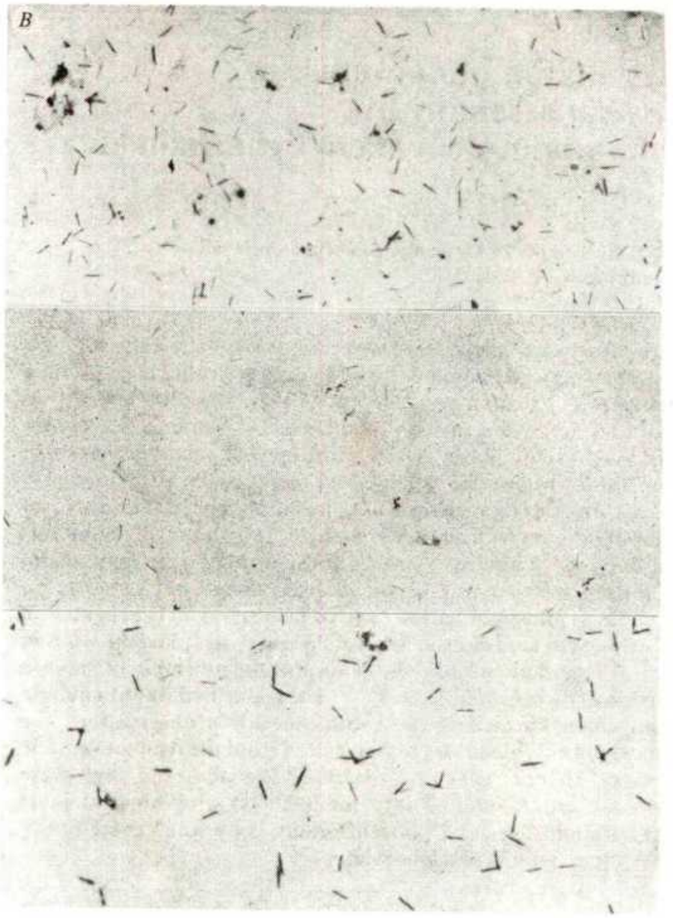

Fig. 2 Induction of thymus myosin filament assembly by phosphorylation of the 20,000-MW, light chain. *A*, Non-phosphorylated myosin filaments (0.46 mg ml^{-1}) were incubated with 25 μg ml^{-1} brain calmodulin in 0.15 M KCl, 10 mM $MgCl_2$, 1 mM EGTA, 0.1 mM DTT and 25 mM imidazole *p*H 7.0. Myosin light chain kinase purified from either chicken gizzard or thymus by calmodulin affinity chromatography[19] was included where indicated. Turbidity was recorded as in Fig. 1. 1 mM [$\gamma^{32}P$]-ATP was added and samples were taken at time points *b* and *c* and the level of myosin phosphorylation determined (Table 1). The specificity of phosphate incorporation into the myosin 20,000-MW light chain was determined by SDS-polyacrylamide gel electrophoresis (PAGE) and subsequent autoradiography (shown in the insets are the 10% acrylamide/SDS gels together with their autoradiograms). The specificity of incorporation was further checked by 8 M urea-PAGE (data not shown). The addition of Mg-ATP caused a rapid drop in turbidity, which remained low until the kinase was activated by addition of $CaCl_2$ to a concentration of 2×10^{-4} M free Ca^{2+}, whereupon a steady increase in turbidity was observed to accompany light chain phosphorylation. In the absence of kinase, there was no light chain phosphorylation or turbidity increase on addition of $CaCl_2$. *B*, Electron micrographs of thymus myosin taken at three critical time points, *a*, *b* and *c* in the assembly assay. Specimens prepared as described in Fig. 1. Top, non-phosphorylated myosin filaments in the absence of ATP; middle, after addition of Mg-ATP to 1 mM, myosin filaments completely disappear, and in their place, a high concentration of dissolved protein is observed on the grid; bottom, after addition of calcium, filaments reappear. ×5,000.

non-muscle and smooth muscle cells exists in a disassembled state, whereas in relaxed vertebrate and invertebrate striated muscles, myosin retains its filamentous organization, in agreement with direct observations on relaxed skeletal muscles[15].

Table 1 Correlation of light chain phosphorylation and actin-activated Mg-ATPase of thymus myosin with filament assembly

Time point during 'assembly assay' (see Fig. 2*A*)	−Kinase mol phosphate per mol light chain	Mg-ATPase (nmol per min per mg)	+Kinase mol phosphate per mol light chain	Mg-ATPase (nmol per min per mg)
1 mM EGTA (Fig. 2*b*)	0.1	4.0	0.25	7.0
2×10^{-4} M Ca^{2+} (Fig. 2*c*)	0.2	4.0	0.75	26.0

Light chain phosphorylation and actin-activated Mg-ATPase activities were determined in conditions identical to those used in the assembly assay at the time points marked *b* and *c* in Fig. 2*A*. The conditions were 25 °C, 0.15 M KCl, 10 mM $MgCl_2$, 0.1 mM dithiothreitol (DTT) and 25 mM imidazole *p*H 7.0. At time point *b*, 1 mM EGTA was present in the buffer, and at time point *c*, 1 mM EGTA and 1.2 mM $CaCl_2$ were present. Myosin phosphorylation was determined by a Millipore filtration method similar to that of Sherry *et al.*[7]. Mg-ATPase activity was determined according to the method of Seals *et al.*[17], after addition of [illegible] actin to a 10-fold weight excess over myosin. At time point *c* the [illegible] phosphorylated the myosin light chain, promoting inter-[illegible] in addition to inducing myosin filament assembly.

Phosphorylation of the 20,000-MW light chain of thymus myosin, disassembled in the presence of Mg-ATP, induces myosin filament assembly. Using calmodulin-dependent light chain kinase purified from either chicken gizzard or calf thymus cells, we have monitored the effect of phosphorylation on the assembly of thymus myosin filaments (Fig. 2). Addition of 1 mM Mg-ATP to non-phosphorylated myosin filaments incubated in the presence of light chain kinase, calmodulin and EGTA, caused a rapid drop in turbidity (Fig. 2*A*). In the electron microscope, the short bipolar filaments which were present before ATP addition are now absent (Fig. 2*B*). The myosin filaments remained disassembled until the kinase–calmodulin complex was activated by the addition of calcium. A steady increase in turbidity and the appearance of bipolar filaments were then observed (average length 5,000±640 Å). The reassembly of the myosin filaments accompanies the phosphorylation of the 20,000-MW light chain (Table 1). In the absence of kinase or calcium, there was no light chain phosphorylation or filament formation. We have observed similar effects with human platelet myosin. These results raise the question of whether phosphorylation regulates myosin filament assembly in all non-muscle cells. Transient assembly of smooth muscle myosin, regulated by light chain phosphorylation, has also been suggested by Suzuki *et al.*[12]. Our results using chicken gizzard myosin are in total agreement with their data. We believe that these findings may be very relevant to the unresolved controversy surrounding the state of myosin in 'relaxed' smooth muscles[16].

Our results suggest that the assembly of myosin filaments may be a crucial step in the pathway leading to non-muscle myosin activation by calmodulin-dependent light chain kinase. However, is it the only step involved in activation, for what contribution does filament assembly make to the observed stimulation of the actin-activated myosin Mg-ATPase activity controlled by light chain phosphorylation (Table 1)? Experiments are in progress to answer this question. Several other important questions remain to be resolved. If myosin filament assembly mediated by phosphorylation is involved in activation, one would predict that relaxation is controlled by dephosphorylation of the myosin and filament disassembly. Experiments are being carried out to test whether the process of filament assembly can be reversed by dephosphorylation of the myosin. How does phosphorylation of a light chain associated with the subfragment-1 region of the myosin modulate the assembly of myosin into filaments, which is generally assumed to be due to interactions between the light meromyosin (LMM) portions of the molecules? To answer this question, we need to know the position of the light chain on the myosin head, the changes that occur when it is phosphorylated or dephosphorylated, and how these changes affect the packing of the myosin molecules in the filament.

In conclusion, we propose that in 'resting' vertebrate non-muscle cells, myosin filaments are absent and are formed transiently during periods of contractile activity. Our observation that the activation process—phosphorylation—generates bipolar myosin filaments provides circumstantial evidence that some type of sliding-filament interaction[15] between actin and myosin may operate in vertebrate non-muscle cells.

We thank Drs H. E. Huxley and P. Wagner for discussion, and Mr P. J. Tooth for preparing gizzard myosin. J.M.S. is a recipient of an MRC studentship, and K.A.T. is a recipient of a post-doctoral fellowship from the Muscular Dystrophy Association.

Endogenous electric field around muscle fibres depends on the Na^+–K^+ pump

W. J. Betz, J. H. Caldwell* & R. R. Ribchester†

Department of Physiology, University of Colorado Health Science Center, Denver, Colorado 80262

K. R. Robinson‡ & R. F. Stump‡

Division of Molecular and Cellular Biology, National Jewish Hospital, Denver, Colorado 80206

We describe here experiments which reveal a new physiological specialization in the endplate (synaptic) region of skeletal muscle fibres. Using a vibrating microelectrode[1] which can detect small currents flowing in extracellular fluid, we have found that the membrane in the endplate region behaves as though a steady positive current is generated in this location. Current re-enters the fibre in the extrajunctional region. Further experiments show that this current is dependent on the activity of the sodium pump. The electric field created by this current may be important for long-term interactions between muscle and nerve.

Most experiments to be described were performed on small (lumbrical and flexor digitorum brevis) muscles of the rat hind foot, although similar results were obtained in a few experiments with mouse soleus and frog sartorius muscles. Experiments were performed *in vitro* at room temperature (23 °C). Muscles were bathed in Krebs solution buffered to pH 7.4 with bicarbonate/CO_2 or HEPES.

The vibrating microelectrode works as follows: a metal-filled glass micropipette with a platinum ball (10–15-μm diameter) electroplated on its tip is attached to a piezoelectric bender, which is driven at a constant frequency (about 260 Hz). Excursion distance of the electrode tip is about 35 μm. The input signal is led to a lock-in amplifier (Princeton Applied Research), which filters (with bandpass equal to the vibration frequency), rectifies and then averages the signal over many cycles to reduce noise further (response time constant was 1–10 s). Thus, the output provides a measure of the peak-to-peak potential difference between the electrode tip at its excursion limits. Each electrode is calibrated with a known current source. Peak-to-peak input voltages were calculated by multiplying d.c. output values by 2/0.707; all values presented in text and figures are peak-to-peak. Potential differences of 0.1 μV can be readily detected. Krebs solution resistivity is 75 Ω cm; thus 0.1 μV corresponds to a current density of about 1 μA cm^{-2}. The electrode vibration was oriented perpendicular to the long axis of the muscle; thus, when adjacent to a muscle fibre, it provided a measure of membrane current at that point. Baseline values were obtained with the electrode vibrating far (several mm) from the muscle.

The spatial distribution of current was mapped along the lateral margin of whole muscles (Fig. 1*a*). Outward current was detected near the middle of the muscle, and the maximum outward current was invariably located at the endplate zone, which was identified by subsequent staining for acetylcholinesterase. In the flanking regions, membrane current reversed direction and flowed inward (Fig. 1*a*; *b*, filled circles). This pattern is drawn schematically in Fig. 1*c*, which also illustrates relative dimensions of the electrode and fibre.

To gain further information about the spatial distribution of current sources and sinks, experiments were repeated on single isolated muscle fibres. Flexor digitorum brevis muscles were incubated in Krebs containing 0.1–0.3% collagenase for 2–3 h, and then triturated to release hundreds of single, intact fibres[2]. The current pattern around single fibres was like that obtained for whole muscles (see Fig. 1*b*, open circles). The peak outward current occurred at the endplate, which could be visually identified on the living cells. In some cases it appeared that the nerve terminals had been completely removed by the isolation procedure. Such fibres still generated an outward current in the endplate region; this identifies the muscle membrane as a source of the current. The amplitude of the signal fell off rapidly as [illegible] electrode was moved away from the muscle fibre, be[illegible]ents, undetectable when the electrode was a few hundred [illegible] the fibre. This suggests that, in the whole muscle

0028-0836/80/380235—03$01.00

only the fibres near the surface contributed to the recorded signal. Maximal outward current at the membrane was estimated to be about 10 μA cm^{-2}, and integration of the current profile around the circumference of the fibre gave a value of total outward current of about 1 nA. In a muscle fibre with an input resistance of 0.5 MΩ, this should produce a hyperpolarization of about 0.5 mV.

Five different kinds of experiments suggest a role for the sodium–potassium pump in the generation of the outward current. In each experiment, whole muscles were used and, after initial spatial mapping, all measurements were made at the site of the maximum outward current density (endplate zone). (1) Effect of potassium removal: when Krebs solution without potassium was perfused through the chamber, the outward current was abolished within 15–30 s (Fig. 2*a*). The effect was readily reversible. The rapidity of these effects suggests again that only fibres near the surface of the muscle contributed to the recorded signal. (2) Effects of temperature: perfusing the chamber with ice-cold Krebs solution caused the current to decrease greatly. Conversely, the signal increased in amplitude when warmed Krebs solution (37 °C) was infused. These results are consistent with the involvement of a pump. (3) Effect of ouabain: the cardiac glycoside ouabain is a specific inhibitor of the sodium pump. When mouse soleus muscle was superfused with Krebs solution containing 0.1 mM ouabain, the current was rapidly abolished. The effect was less clear with rat muscle; 10 mM ouabain reduced, but did not abolish the signal. Rat muscle, however, is known to be relatively resistant to ouabain[3]. (4) Effects of sodium replacement: external sodium was completely replaced by lithium. Lithium ions can enter muscle cells, but are not pumped out by the Na$^+$–K$^+$ pump. The Li solution reversibly abolished the current over a period of several minutes. This effect was probably due to a gradual reduction of internal sodium concentration, so that the Na$^+$–K$^+$ pump was no longer active. (5) Sodium 'loading' in the endplate region (Fig. 2*b*). Intracellular sodium concentration in the endplate region was increased by perfusing with Krebs solution containing acetylcholine (ACh, 5×10^{-4}g ml^{-1}) or carbachol (3×10^{-5}g ml^{-1}). These substances activate ACh receptors, whose distribution is restricted to the membrane in the endplate region, and which, when activated, produce an influx of sodium ions. The presence of these drugs changed the current recorded in the endplate region from outward to an extremely large inward current, reflecting the entry of sodium ions. When the preparation was subsequently perfused with Krebs solution containing curare (1×10^{-5}g ml^{-1}) or α-bungarotoxin (4×10^{-6}g ml^{-1}) and no ACh or carbachol, the ACh receptors were blocked, and the recorded current reversed again, becoming about four times larger than normal. (Control experiments showed that curare, α-bungaro-

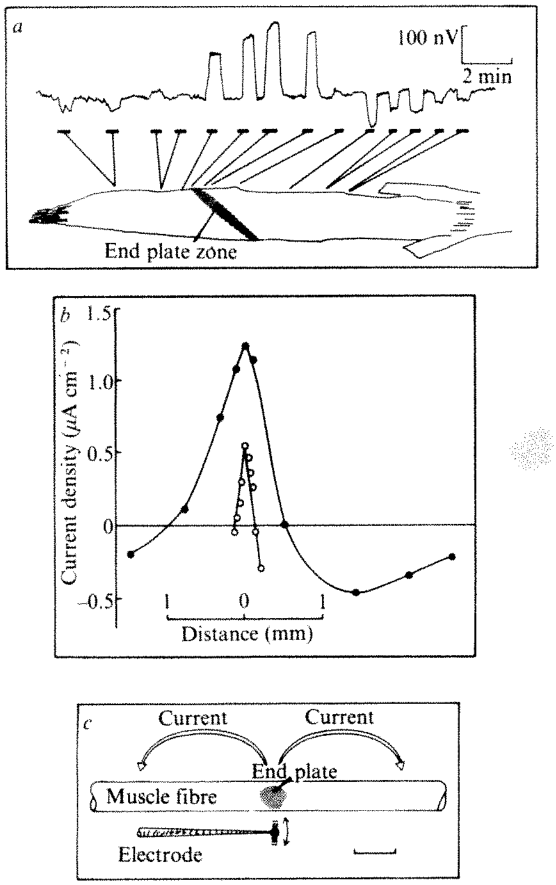

Fig. 1 *a*, Current pattern around whole muscle. The electrode, vibrating continuously, was alternately moved close to the muscle (marked by bars) and then away to a remote reference position in the bath. Recording positions near the muscle are shown by lines connecting the bars to the drawing of the muscle; the stippled area in the drawing marks the endplate zone. The current was largest when the electrode was at the endplate zone, and reversed sign in the flanking regions. Upward deflection represents outward current. The electrode was vibrated perpendicular to the long axis of the muscle (see *c*). *b*, Amplitude of the current (recorded near the muscle) is plotted as a function of distance from the endplate region. Results from ●, an experiment on a whole muscle, and ○, an isolated muscle fibre. *c*, Schematic diagram of a single muscle fibre depicting endogenous current pattern. The electrode tip and le fibre are drawn to illustrate approximate scale (bar ≃ 50 μm).

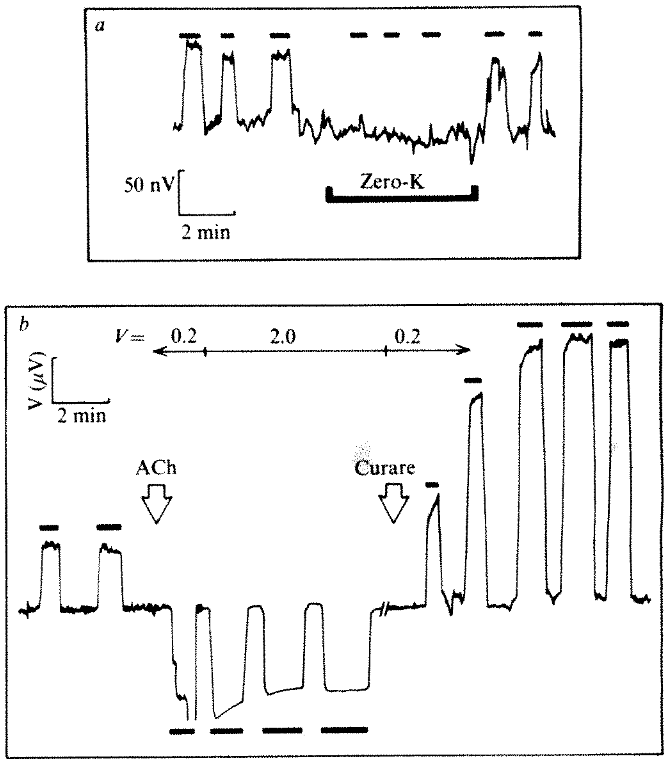

Fig. 2 *a*, Continuous recording obtained during an experiment to test the effect of removal of external potassium ions. During the times marked by the bars, the electrode was close to the muscle, at the endplate zone. Note that the endogenous current was abolished in zero-K Krebs (upward deflection = outward current). *b*, Experiment to test the effect of 'sodium loading' of the endplate region. Recordings near the muscle (marked by bars), were made at the endplate region. After the first two control readings, the chamber was perfused with Krebs containing ACh (plus prostigmine), and the current reversed sign, becoming inward and very large (note 10-fold gain change). When the chamber was later perfused with Krebs containing curare, the current again became outward, and was about fourfold larger than control. All solutions contained tetrodotoxin; the time break represents about 20 min.

toxin, and tetrodotoxin by themselves had no effect on the normal outward current). The increased amplitude of the outward current is consistent with a more active Na$^+$ pump, due to the increased internal sodium concentration.

The results of these experiments lead to the conclusion that the steady currents which were measured are produced or maintained by the Na$^+$–K$^+$ pump. The existence of such pumps and their electrogenicity in skeletal muscle are known[4]. The new finding reported here is the non-uniform spatial distribution of membrane current sources and sinks. This must reflect either a non-uniform distribution of pumping activity (that is, pumps that are more concentrated, more active, or more electrogenic in the endplate region) or a non-uniform distribution of leakage channels, or both. One hypothesis is that there is a higher concentration of electrogenic Na$^+$–K$^+$ pump sites in the endplate region than elsewhere, reflecting the need for removal of sodium ions that enter the fibre through ACh channels during nerve-evoked excitation. However, the outward current persisted *in vitro* for several hours in the absence of nerve-evoked activity (even after ACh receptors were totally blocked by curare or α-bungarotoxin), suggesting that the currents measured in our experimental conditions were independent of fluxes through ACh channels.

Whatever the distribution of pumps and leaks, their non-uniformity produces an electric current and hence an electric field, whose focus is centred on the endplate region. It is naturally of interest to inquire whether this field might serve other functions. For instance, it has recently been shown that ACh receptor distribution on myotubes[5] and growth of neurites in culture (ref. 6, and McCaig, Robinson and Hinkle, unpublished observations) can be affected by externally applied electric fields. This raises the possibility that the endogenous electric field reported here might be significant for long term interactions between neurones and muscle fibres. The estimated peak value of the electric field we measured around single, isolated muscle fibres is one to two orders of magnitude smaller than the fields required for effects on ACh receptor distribution or neurite growth in the studies cited above. However, those conditions and preparations were considerably different from the ones reported here. Moreover, the electric field which exists deep within an intact muscle may be larger than that measured near an isolated fibre. For instance, both the restricted volume of extracellular space and the presence of many endplates lying in register would serve to increase electric field strength.

Active sodium transport by turtle colon via an electrogenic Na–K exchange pump

Kevin L. Kirk, Dan R. Halm & David C. Dawson

Department of Physiology and Biophysics, University of Iowa College of Medicine, Iowa City, Iowa 52240

Active sodium absorption by a variety of epithelia is abolished by ouabain, but the obligatory coupling between the movement of sodium and potassium expected from a basolateral (Na$^+$+K$^+$) ATPase has not been convincingly demonstrated[1]. According to the model of Koefoed-Johnsen and Ussing[2], the asymmetric cation selectivities of the apical and basolateral membranes prevent basolateral Na–K exchange from being expressed as opposing transmural ion flows. An additional consequence of this asymmetry is that the short-circuit current (I_{SC}) cannot be identified with the current through the sodium–potassium pump. We used the polyene antibiotic, amphotericin-B, to reduce the resistance and the cation selectivity of the apical membrane of isolated turtle colon so that the basolateral membrane current could be dissected into two components: one through a barium-sensitive potassium channel and another which represents the current associated with ouabain-sensitive, electrogenic, Na–K exchange. Comparison of cation fluxes and short circuit current indicates that in these conditions active sodium absorption is entirely attributable to an electrogenic Na–K pump with a stoichiometry of approximately 3Na:2K.

The presence of a basolateral membrane potassium channel was established by allowing tissues to attain a steady state I_{SC} and then subjecting them to the following sequence of manoeuvres. The steady-state I_{SC} was virtually abolished with ouabain (10^{-4} M, serosal) and then amiloride (10^{-4} M) was added to the mucosal bathing solution. Subsequently, the potassium concentration of either the mucosal or serosal bathing solution was raised to 10–30 mM by the addition of a small volume of concentrated potassium methyl sulphate or KCl. These additions had virtually no effect on I_{SC} although total tissue conductance (G_T) usually increased slightly, presumably due to an increase in the conductance of the paracellular shunt path[3,4]. Figure 1 shows the results of a representative experiment in which amphotericin-B (6 µM) was added to the mucosal bathing solution in the presence of a mucosal to serosal potassium gradient (M:30 mM, S:3.0 mM). Addition of the polyene produced a prompt increase in I_{SC} and G_T. The steady-state I_{SC} was consistent with net cation flow from mucosa to serosa and, as indicated in the figure, was abolished by the addition of BaCl$_2$ (5 mM) to the serosal bath. The polyene-induced increase in I_{SC} was always consistent with the orientation of the applied potassium e.m.f.

To determine the properties of the ouabain-sensitive active cation transport mechanism, portions of isolated colon bathed by identical solutions containing 102 mM Na and 2.5 mM K were subjected to the following procedure. First amiloride (10^{-4}M) was added to the mucosal side to reduce I_{SC} to near zero

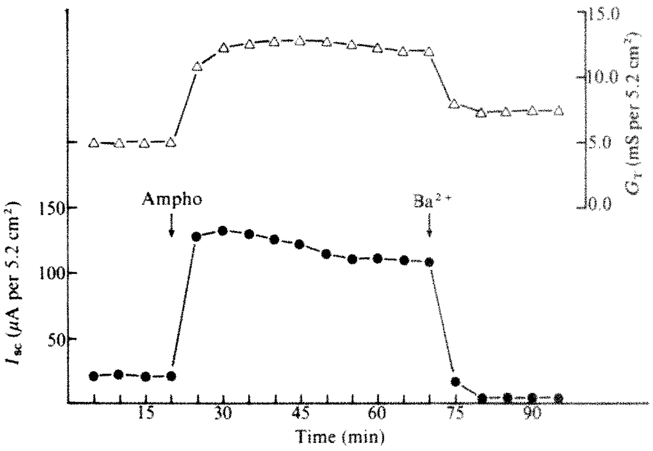

Fig. 1 Portions of stripped turtle colon were mounted in Ussing chambers (area 5.2 cm^2) and bathed on both sides by solutions containing (in mM) sodium benzene sulphonate 100, potassium bicarbonate 2.5, calcium chloride 1.0, sodium pyruvate 2.0, and glucose 5.0. Both solutions were stirred with air so that the *p*H at room temperature was approximately 8.4. Benzene sulphonate was substituted for chloride in an attempt to prevent cell swelling due to net salt movement into epithelial cells in the presence of the polyene[6]. The figure shows short-circuit current (●) and total tissue conductance (△) as a function of time. Active sodium absorption was abolished by adding ouabain (10^{-4} M) to the serosal bath. In the presence of a transmural potassium gradient (M 30 mM, S 2.5 mM) the addition of amphotericin-B (6 µM) increased I_{SC} and G_T. Subsequent addition of BaCl$_2$ (5 mM) to the serosal bath abolished I_{SC} and reduced G_T.

0028-0836/80/380237—03$01.00

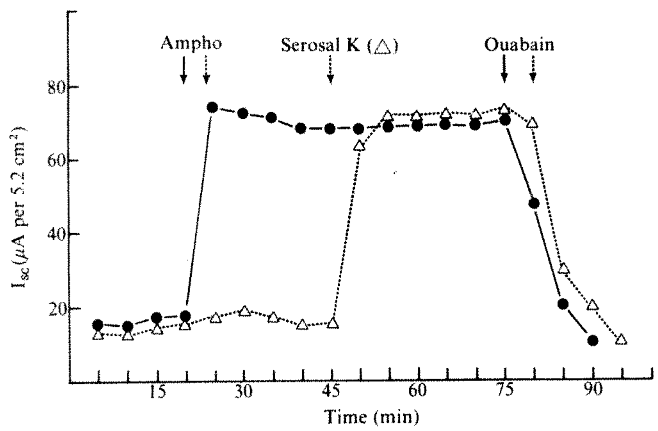

Fig. 2 Short-circuit current as a function of time for colons bathed initially by potassium-containing (●) and potassium-free (△) solutions. I_{SC} was inhibited with mucosal amiloride (10^{-4} M), and $BaCl_2$ (5 mM) was added to the serosal bath. Mucosal amphotericin-B (6 μM) increased I_{SC} only in the presence of serosal potassium. Subsequent addition of potassium to the K-free tissue (△) resulted in a prompt increase in I_{SC}. In both tissues I_{SC} was abolished by ouabain (10^{-4} M).

and abolish sodium absorption[2], then $BaCl_2$ (5 mM) was added to the serosal bath to decrease basolateral potassium conductance. Figure 2 (closed circles) shows the result of a representative experiment in which amphotericin-B (6 μm) was added to the mucosal bath. Addition of the polyene in the absence of electrochemical gradients produced a prompt increase in I_{SC} to a new steady state consistent with net positive charge movement from mucosa to serosa. The polyene-induced I_{SC} was stable for more than 60 min and was abolished by serosal ouabain (10^{-4} M).

The ouabain-sensitive, polyene-induced I_{SC} exhibited an obligatory dependence on serosal potassium. The triangles in Fig. 2 represent a tissue initially bathed on the serosal side by potassium-free, Na benzene sulphonate Ringer's. The addition of amphotericin-B had virtually no effect on I_{SC}; however, subsequent addition of KCl (2.5 mM) to the serosal bath resulted in a prompt increase in I_{SC} to a level virtually identical to that of the control. A further increase in serosal potassium concentration (data not shown) produced an additional increase in I_{SC} suggesting that in these conditions the pump rate is limited by the supply of serosal potassium.

Figure 3 shows the results of a similar experiment designed to evaluate the dependence of the polyene-induced I_{SC} on mucosal sodium. Both tissues were bathed initially on the serosal side by benzene sulphonate Ringer's containing 102 mM Na and 2.5 mM K; and on the mucosal side by Ringer's which was identical except that the sodium benzene sulphonate had been replaced with choline benzene sulphonate containing less than 1 mM sodium. Both mucosal solutions contained amiloride and in one tissue (closed circles) the mucosal sodium concentration was raised to 20 mM by the addition of a small volume of concentrated Na benzene sulphonate. Subsequent addition of amphotericin-B to both tissues produced a prompt increase in I_{SC} only in the tissue exposed to a sodium-containing mucosal solution. Addition of sodium to the second tissue (triangles), however, increased I_{SC} to a level comparable to the first. The amphotericin-induced I_{SC} in both tissues was abolished by ouabain.

Table 1 Amphotericin-induced sodium absorption, potassium secretion and short-circuit current

	ΔI_{SC} (μequiv. cm^{-2} h^{-1})	ΔJ_{net} (μequiv. cm^{-2} h^{-1})	$\Delta J_{net}/\Delta I_{SC}$	n
Sodium	0.67±0.04	2.00±0.16	3.01±0.15	15
Potassium	0.57±0.11	1.14±0.20	2.12±0.14	8

Fluxes of ^{22}Na were measured using mucosal and serosal solutions which were identical Na benzene sulphonate Ringer's in which the potassium concentration had been raised to 14 mM in order to increase I_{SC} in the presence of the polyene. The mucosal bath contained amiloride (10^{-4} M) and the serosal bath contained $BaCl_2$ (5 mM). Net sodium fluxes were obtained by comparing unidirectional fluxes from paired tissues. Preliminary experiments revealed that ^{42}K fluxes significantly underestimated net potassium flux, hence net potassium secretion was determined by using flame photometry to measure the appearance of the ion in a nominally potassium-free mucosal bathing solution which also contained amiloride (10^{-4} M). The serosal solution contained 10 mM potassium and 5 mM $BaCl_2$. Otherwise both solutions were identical sodium benzene sulphonate Ringer's. The values appearing in the table (mean ±s.e.) were corrected for the small diffusional potassium flux which could be estimated by measuring potassium appearance before the addition of the polyene.

In view of the striking dependence of the ouabain-sensitive, amphotericin-induced I_{SC} on serosal potassium and mucosal sodium we measured transmural fluxes of these ions to determine the ionic basis of the current. The results are shown in Table 1 where the amphotericin-induced increases in net sodium absorption and potassium secretion are shown along with the corresponding amphotericin-induced increases in I_{SC}. The results indicate that net Na absorption is approximately three times I_{SC} whereas net potassium secretion is about twice I_{SC}, so that the transepithelial current can be attributed to the difference between the net fluxes of the two cations. Previous studies on lipid bilayers[5], red blood cells[6] and isolated epithelia[7-9] have suggested that the polyene antibiotics can form pores in natural and artificial membranes which are moderately cation selective but do not discriminate appreciably between sodium and potassium. Neilsen[6] recently used the polyene antibiotic, filipin, to reduce the cation selectivity of the apical membrane of frog skin and obtained results consistent with the existence of a sodium–potassium exchange pump. In these experiments, however, the 'pump current' and its relation to active cation fluxes was not clearly defined.

In the presence of mucosal polyene, the transport properties of the turtle colon appear to be dominated by the properties of the basolateral membrane which must contain at least two cation transport elements: a barium-sensitive potassium conductance and an electrogenic sodium–potassium exchange pump. In the presence of serosal ouabain and mucosal polyene the turtle colon is markedly potassium selective, and this potassium

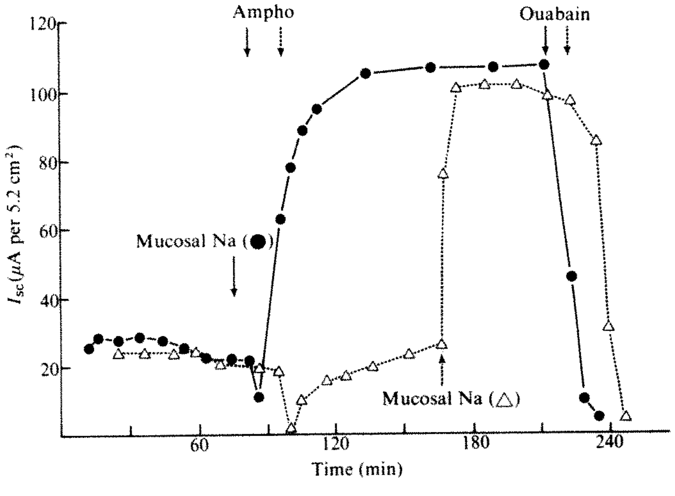

Fig. 3 Short-circuit current as a function of time for tissues bathed initially by sodium-free mucosal solutions and treated with amiloride (mucosal bath) and $BaCl_2$ (serosal bath). After the addition of sodium (20 mM) to the mucosal solution of one (●), amphotericin-B was added to the mucosal solution of both tissues. I_{SC} increased only in the presence of mucosal sodium. Subsequent addition of mucosal sodium to the Na-free tissue (△) resulted in a prompt increase in I_{SC}. In both tissues I_{SC} was abolished by ouabain.

conductance is blocked by serosal Ba^{2+}. This result is consonant with Nagel's report[10] of a Ba^{2+}-sensitive potassium conductance in the basolateral membrane of isolated frog skin. Additional experiments (data not shown) indicate that serosal Ba^{2+} also reduces ^{42}K fluxes across the epithelium in similar conditions. If ouabain is omitted from the serosal bathing solution, amphotericin-B induces a short-circuit current in the absence of transmural cation gradients. This 'active' I_{sc} exhibits an obligatory dependence on mucosal sodium and serosal potassium, is abolished by ouabain, and is numerically equal to the difference between net Na absorption and potassium secretion. These observations suggest that in the presence of serosal Ba^{2+} the polyene-induced I_{sc} represents current attributable to an electrogenic sodium–potassium exchange, where the ratio of sodium to potassium is approximately 3Na : 2K. Thus, sodium absorption by the turtle colon seems to be entirely attributable to the presence, in the basolateral membrane, of a ouabain-sensitive cation exchange pump similar to that which seems to exist in human red blood cells[11,12] and in some excitable membranes[13].

This research was supported by grants from NIH(AM18776) and the Iowa Heart Association (79-G-7).

Light-induced changes in membrane current in cone outer segments of tiger salamander and turtle

Julie L. Schnapf*

Laboratory of Neurophysiology, NINCDS, National Institutes of Health, Bethesda, Maryland 20014

Robert N. McBurney

Department of Physiology, The Medical School,
Newcastle upon Tyne NE1 7RU, UK

The peak change in membrane conductance of vertebrate photoreceptors in response to the isomerization of a single photopigment has been estimated from recordings of membrane potential to be about 8 pS in rods[1] and 6 pS in cones[2]. For rods the estimate has been largely confirmed by Yau *et al.*[3] by directly recording membrane current responses of rod outer segments to single photoisomerizations. However, no similar measurements have been reported for cone outer segments. Here, we report on direct recordings of membrane currents of single cone outer segments using an extracellular patch electrode. The technique was similar to that described by Yau *et al.*[3] for toad rods. We have measured dark currents of up to 40 pA, and calculate that the conductance change resulting from a single photoisomerization is less than 1 pS.

A portion of the back of the eye of a dark-adapted larval tiger salamander, *Ambystoma tigrinum*, or turtle, *Pseudemys scripta elegans*, was placed vitreal side down on Millipore filter paper. The sclera and pigment epithelium were gently lifted off, leaving the retina, receptor side up, attached to the filter paper. A 300-μm slice of retina and filter paper was submerged in oxygenated Ringer[4] in a superfusion chamber placed side-on under the water-immersion objective of a conventional microscope, and viewed through an IR image converter at ×600 magnification. The outer segment of a single cone was drawn into a Ringer-filled electrode. The resultant high resistance seal made between the electrode interior and the base of the outer segment of a tiger salamander cone, or between the electrode and a red oil droplet of a turtle cone, enabled us to record 50–90% of the membrane current of the outer segment. Measurements of the relative spectral sensitivities of both these receptors in membrane current per incident photon were consistent with cones containing a dehydroretinal-based pigment with an absorption maximum at 620 nm (refs 5, 6). Current was recorded by a virtual ground current-to-voltage converter with a 100 MΩ feedback resistor.

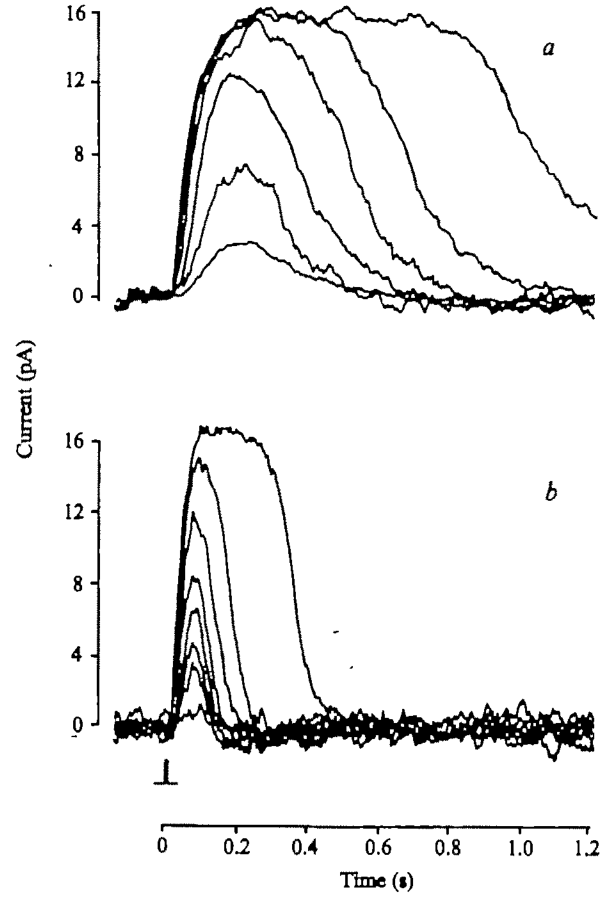

Fig. 1 *a*, Current responses of 'red' cone outer segment of tiger salamander to 10-ms flashes of diffuse white light of increasing intensity; stimulus monitor below. Downward deflection corresponds to inward membrane current, recorded with a d.c. – 10 Hz bandwidth. Average number of effective photoisomerizations per flash, from bottom to top: 3.89×10^2, 1.39×10^3, 3.90×10^3, 1.05×10^4, 3.10×10^4, 3.10×10^5. Stimulus calibration described in Fig. 2. Each trace represents the average of one to nine light responses. The traces shown are uncorrected current records representing, on our estimation, 78% of the true current flowing across the outer segment membrane within the recording electrode. The percentage of membrane current recorded equals the difference in resistance to ground of the electrode with and without the outer segment drawn inside, divided by the resistance of the electrode with the outer segment inside. *b*, Current responses of 'red' cone outer segment of turtle to 10-ms diffuse test flash, bandwidth, d.c. – 10 Hz. Number of effective photoisomerizations estimated per flash, from bottom to top: 1.5×10^2, 6.45×10^2, 1.22×10^3, 1.50×10^3, 2.07×10^3, 4.42×10^3, 1.60×10^4, 1.40×10^5. White light was used for responses 1, 3, 7 and 8; other responses were to red light of $\lambda_{max} = 610$ nm.

Uncorrected current records representing 65% of the true current.

In the dark, a current of up to 40 pA flowed into the outer segments of cones (about 30 pA averaged over the cones sampled). The current was transiently reduced by a brief flash of light. This is illustrated in Fig. 1*a* for a tiger salamander cone and Fig. 1*b* for a turtle cone. A bright light that elicits a saturating response turns off the dark current completely. The time course of the current response seen in salamander cones was very similar to the voltage response of salamander cones reported by other workers[7], and was also similar in waveform to current responses in *Iguana* cones as measured with pairs of extracellular voltage electrodes[8]. However, current responses of turtle cones to bright flashes lacked the initial transient seen in corresponding voltage responses[2]. We suggest that, as in toad rods[3], the voltage transient seen in turtle cones is due to a voltage-sensitive conductance not located in the outer segment. The relationship between peak change in membrane current, I_p, and light intensity, L, was satisfactorily fitted by a Michaelis–Menten equation of the form $I_p/I_{\max} = (1 + S/L)^{-1}$, where $I_{\max}$ is the maximum change in membrane current and S is the number of incident photons required to produce a half-maximal change in membrane current, as shown in Fig. 2. In six experiments in turtle and tiger salamander, the average number of photoisomerizations needed to elicit a half-maximal response, S^*, was 2,150 (range 1,350–2,750). The method for converting light intensity in incident photons, L, to photoisomerizations, L^*, is given in Fig. 2 legend.

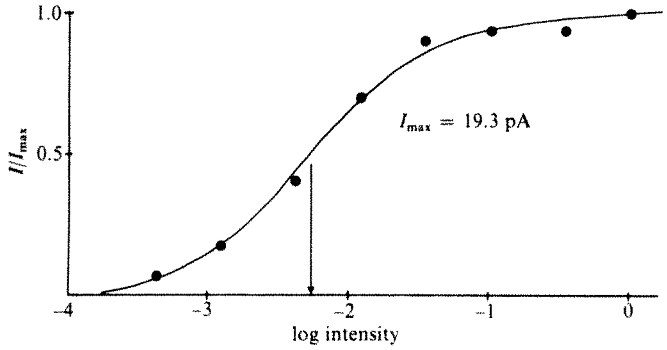

Fig. 2 Peak change in membrane current recorded from a turtle cone outer segment as a function of the intensity of a white, 10-ms test flash. For the cell shown in Fig. 1*a*. Intensity is displayed in log units relative to the maximum unattenuated stimulus. The calculated number of effective photoisomerizations for the unattenuated test light was 3.10×10^5 per flash. The value of the maximum current response, $I_{\max}$, was adjusted to compensate for signal attenuation due to current shunt through the sealing resistance between the electrode and the outer segment. Continuous curve is drawn from a template which described a Michaelis–Menten equation. The arrow, indicating the parameter S, is $10^{-2.26}$ of the unattenuated flash, corresponding to 1.70×10^3 effective photoisomerizations (S^*). From the Michaelis–Menten equation, the response to a single effective photon would be $19.3\ (1 + 1.70 \times 10^3) =$ 0.011 pA. For narrow band spectral stimuli (width at half amplitude = ± 5 nm), the number of photons per μm^2 at all attenuation settings were measured by putting a photodiode (United detector 101A) in place of the retina. The number of effective photoisomerization per test flash, L^*, was estimated by the equation $L^* = 2.3\beta(\lambda)VfLt$, where L is the light intensity in incident photons per μm^2 per s, t is the duration of the test flash, $\beta(\lambda)$ is the specific density of the cone pigment for unpolarized light of wavelength λ (refs 5, 6), V is the volume of the outer cone segment as calculated by measuring the outside dimensions of the cone with an eyepiece micrometer, and f is the fraction of absorbed photons that produced a change in membrane current. The fraction f, estimated as 0.5, was determined by substituting a toad retina for the turtle retina, counting the number of single current 'bumps' (L^*) elicited in a rod by dim light flashes, and dividing by the number of photons absorbed ($2.3\beta(\lambda)VLt$). To calculate photoisomerizations for a 'white' test flash, the intensity of a narrow band stimulus was adjusted so that the current response elicited by this test flash matched that to the white flash. L^* was then calculated from the above equation.

There was no detectable current response to dim flashes where approximately one photoisomerization was elicited per cone. This is not surprising because the substitution of $L^* = 1$ in the Michaelis–Menten equation $I_p/I_{\max} = (1 + S^*/L^*)^{-1}$, with $S^* = 2{,}150$, yielded an average value for the peak change in membrane current per photoisomerization of only 0.013 pA or 0.05% of the maximum current. Our recording system would have been unable to detect such a small change in current. Using a value of 30 mV (refs 2, 7, 9, 10) for the driving force on the membrane current in the dark, we calculate an average decrease in outer segment membrane conductance at the peak of a single photon response of 0.43 pS.

The fraction, B, of channels closed by a single photoisomerization can be determined from the equation $B = (1 + S^*\alpha)^{-1}$, where S^* is as before and α is the ratio of the membrane conductance of a cone during a saturating response and its membrane conductance in the dark[2]. Taking our average value of 2,150 for S^* and an estimate for α of 0.67 (refs 2, 7), for dim flashes each effective photoisomerization blocks 0.07% of the available channels. This is about half the value obtained by Baylor *et al.*[2] based on voltage recordings of turtle cones. The difference may reflect a greater light-adapted state in this preparation. Assuming that this is the case, a single photoisomerization can be expected to elicit approximately a 10–12-μV change in membrane potential[15], and taken with a 0.013-pA current event, this yields an input resistence of an isolated cone of about 800–900 MΩ. This value is close to the value estimated for the input resistance of isolated rods[3,11], but is larger than that previously estimated for turtle cones on the basis of their spatial sensitivity profiles[12].

In response to a step increase in illumination, we observed that the suppression of inward current reached a maximum and then dropped to a plateau in seconds, as shown in Fig. 3 for a light that transiently suppressed all the dark current. The time course of the decay depended on light intensity. Calculations based on those by other workers[13] show that the decrease in quantum catching resulting from photopigment bleaching at these intensities has an insignificant role in the decay of the response to steps of light. On the basis of records obtained with the procedure illustrated in Fig. 3, we suggest that the most likely explanation for the decay in the current response is a reopening of outer segment ion channels that were initially closed during the peak of the response. At about 50 s after the onset of the light, when the current response had decayed and was maintained at a steady plateau level, the light intensity was increased. We observed a further reduction in membrane current. It seems that during the development of the plateau phase a population of unblocked channels had appeared and these were now available to be blocked by a process generated by the arrival of more photons. We suggest that these channels are derived from those blocked during the initial saturating phase of the response.

It has been reported for turtle cones that fluctuations in membrane potential around the mean value in the dark are substantially reduced when the cell is hyperpolarized by bright lights[9]. In weakly coupled cones, a decrease in the standard deviation, σ_v, of membrane voltage fluctuations of as much as 0.66 mV, or 5–6% of the maximum light response, has been observed. We are unable to support the suggestion that this noise is generated in the outer segment. If the voltage fluctuations were due to conductance fluctuations in the outer segment, the reduction in the standard deviation of the current elicited by light should also be 5–6% of the maximum light response, or about 2 pA. Although we have measured some changes in the fluctuations associated with records of outer-segment membrane current between darkness and various levels of illumination, we have not seen a reduction in current noise as large as that predicted from the records of voltage fluctuations of isolated cones. The largest reduction we observed in the standard deviation of the current going from darkness to a saturating light intensity was 0.37 pA in a 38-pA cone, or about 1% of the total current (after compensation for the current shunt through the sealing resistance, bandwidth = d.c. – 10 Hz). As the state of adaptation of the two preparations seem comparable (judging from estimates of S^*), we conclude that a sizeable portion of the reported fluctuations in voltage is not generated in the outer segment.

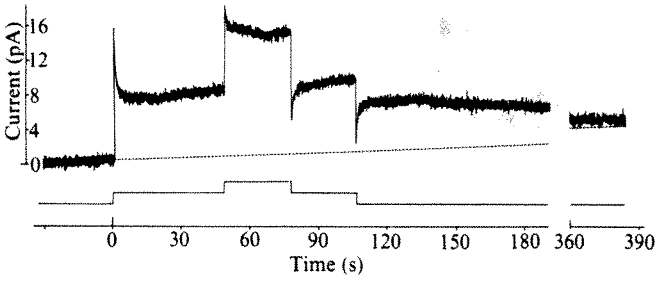

Fig. 3 The current responses of a turtle cone outer segment to steps of light (bandwidth, d.c. – 10 Hz). Uncorrected records representing an estimated 65% of the true current. Stimulus monitor shown below. Steps of illumination correspond to 6.80×10^4 followed by 2.18×10^5 photoisomerizations per s.

We cannot be sure that the current fluctuations we have observed are associated with the phototransduction process. The changes in variance are very small and not measurable in some recordings (especially recordings where the sealing resistance is low and consequently the baseline current noise is high). If the dark current noise that can be abolished in bright light is due to random fluctuations in the number of open ionic channels and these channels can be closed by light, the current i, flowing through each open channel, can be estimated from the equation $i = \sigma_I^2/(\overline{\Delta I}\cdot p)$, where σ_I^2 is the difference between the current variance in the dark and at the peak of a saturating response, $\overline{\Delta I}$ is the mean change in current and p is the proportion of these channels that are already closed in the dark. Using our corrected values $\sigma_I^2 = 0.14$ pA^2 and $\overline{\Delta I} = 38$ pA from one turtle cone and taking $p = 0.3$ (ref. 14), we calculate a single channel current of 0.012 pA. This value is close to estimates of the size of the elementary current event underlying dark noise in rods[1,14]. A comparison between this value and our estimate of the current change produced by a single photoisomerization in dim lights leads us to suggest that if this current noise is generated by fluctuations of light-sensitive channels in the outer segment, a single photoisomerization causes the closure of about one channel.

Specific dephosphorylation of membrane proteins in Rous sarcoma virus-transformed chick embryo fibroblasts

Daniel P. Witt & Julius A. Gordon

Department of Pathology, University of Colorado Health Sciences Center, Denver, Colorado 80262

Chick embryo fibroblasts (CEF) infected with avian sarcoma virus become rapidly transformed as a result of expression of the viral *src* gene[1,2] in the form of a single polypeptide of molecular weight 60,000 (pp60^{src})[3] with protein kinase activity[4] and suggested preferential association with the plasma membrane[5,6]. Studies with normal avian and mammalian cells have revealed the presence of an antigenically related protein[7,8] which seems to have similar kinase activity, but which is present at less than 1% of the levels of virally induced *src* protein found in transformed cells[8,9]. As dynamic protein phosphorylation is important in numerous regulatory processes[10,11], the phenotypic expression of transformation may arise from an imbalance in one or more regulatory mechanisms that are controlled by protein phosphorylation[4,8,12]. The cell membrane is affected during transformation[13], including its phosphotransferase activity[14,15]. The latter has been shown using isolated membrane fractions whose properties may be changed during preparation[16]. Therefore, we have compared the phosphorylation state of individual membrane proteins found in intact normal and RSV-transformed cells and report here the identification of two heavily phosphorylated, acidic membrane proteins in normal CEF which are specifically dephosphorylated on transformation by wild-type and temperature-sensitive Rous sarcoma viruses.

Normal and transformed chick fibroblasts were metabolically labelled with ^{35}S-methionine, and membranes were prepared by the method of Brunette and Till[17] and analysed by two-dimensional gel electrophoresis. Two proteins of molecular weights 57,000 and 55,000 (57 K and 55 K proteins) and similar isoelectric point (~5.1) were identified as being almost exclusively associated with the membrane preparations (Fig. 1). That the membrane association was not an artefact of preparation was supported by the presence of these proteins in membranes prepared by sucrose density centrifugation (Fig. 1*c*, ref. 18). When normal cells (or cells infected with RAV-2, which does not contain the *src* gene) were incubated with ^{32}P-P$_i$, both proteins became heavily labelled within 2 h (Fig. 2*a*). In contrast, transformed cells labelled in identical conditions showed very little net incorporation of phosphate by these proteins (Fig. 2*c*). Quantification of both proteins by ^{35}S-methionine incorporation over 17 h suggested that any apparent net reduction in these proteins following cell transformation was insufficient to account for the dramatic decrease in phosphorylation. Normal cells and cells infected with RAV-2 virus showed no cell density dependence of phosphorylation of these proteins (data not shown).

We examined the turnover of phosphate on these proteins by means of a pulse-chase study (Fig. 2). Normal cells labelled with ^{32}P-P$_i$ for 2 h (Fig. 2*a*) and chased for 4 h (Fig. 2*b*) showed a marked decrease in label associated with intermediate filament protein (IFP) and most other phosphoproteins, some increase in a 87 K protein, but no apparent decrease in the isotope associated with either the 57 K or 55 K proteins. This suggests that phosphatase activity specific for these phosphoproteins is limited in the normal cell or that these proteins are found in a privileged location that is inaccessible to general phosphatase activity. In contrast, little label is detected in these proteins at either time point in RSV-transformed cells (Fig. 2*c*, *d*). Other

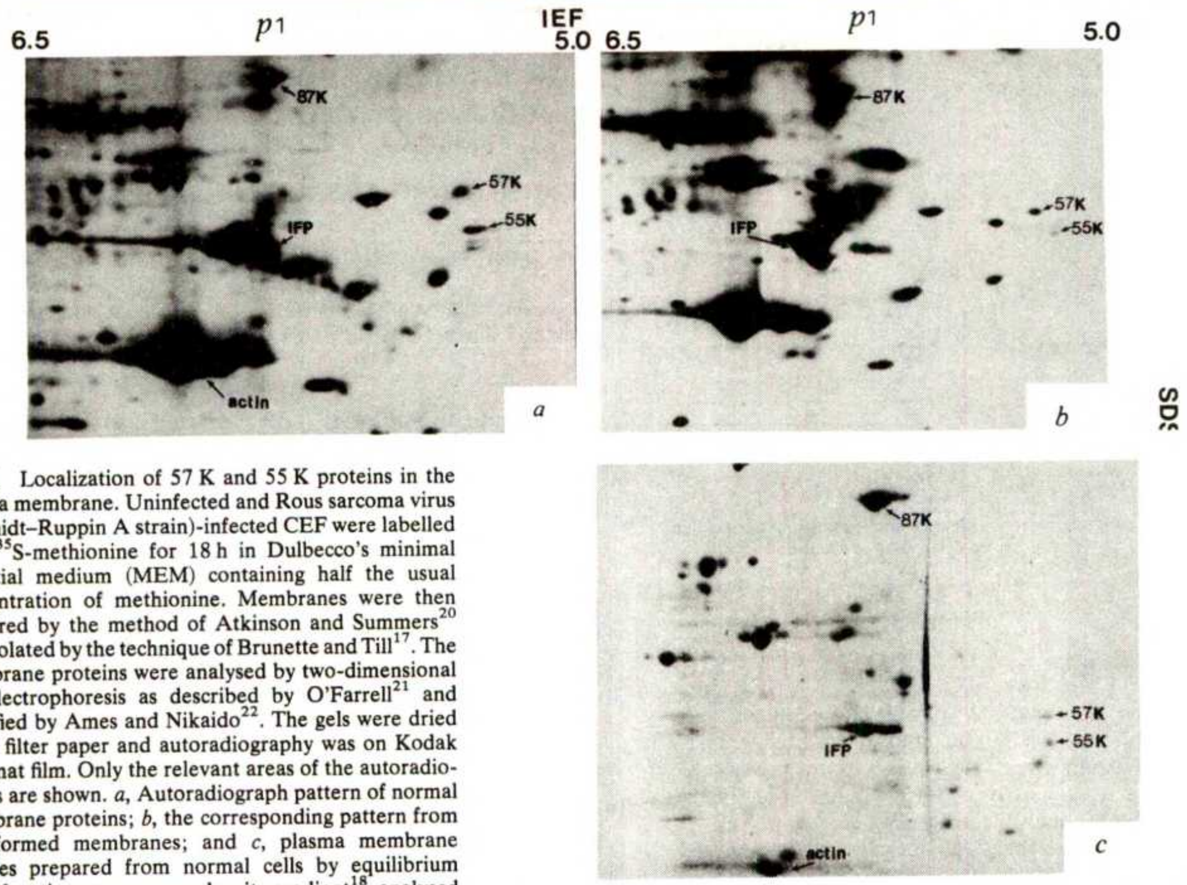

Fig. 1 Localization of 57 K and 55 K proteins in the plasma membrane. Uninfected and Rous sarcoma virus (Schmidt–Ruppin A strain)-infected CEF were labelled with ^{35}S-methionine for 18 h in Dulbecco's minimal essential medium (MEM) containing half the usual concentration of methionine. Membranes were then prepared by the method of Atkinson and Summers[20] and isolated by the technique of Brunette and Till[17]. The membrane proteins were analysed by two-dimensional gel electrophoresis as described by O'Farrell[21] and modified by Ames and Nikaido[22]. The gels were dried on to filter paper and autoradiography was on Kodak X-Omat film. Only the relevant areas of the autoradiograms are shown. *a*, Autoradiograph pattern of normal membrane proteins; *b*, the corresponding pattern from transformed membranes; and *c*, plasma membrane vesicles prepared from normal cells by equilibrium centrifugation on a sucrose density gradient[18], analysed in a similar fashion, and stained with Coomassie blue. It is apparent that there is some degree of association of structural proteins, that is, intermediate filament protein (IFP) and actin, with membranes, particularly those prepared by the Brunette and Till method[17]. The 57 K and 55 K proteins are invariably found to be membrane associated by both techniques. The presence of the 57 K and 55 K proteins could not be detected in the 100,000*g* supernatant from these preparations.

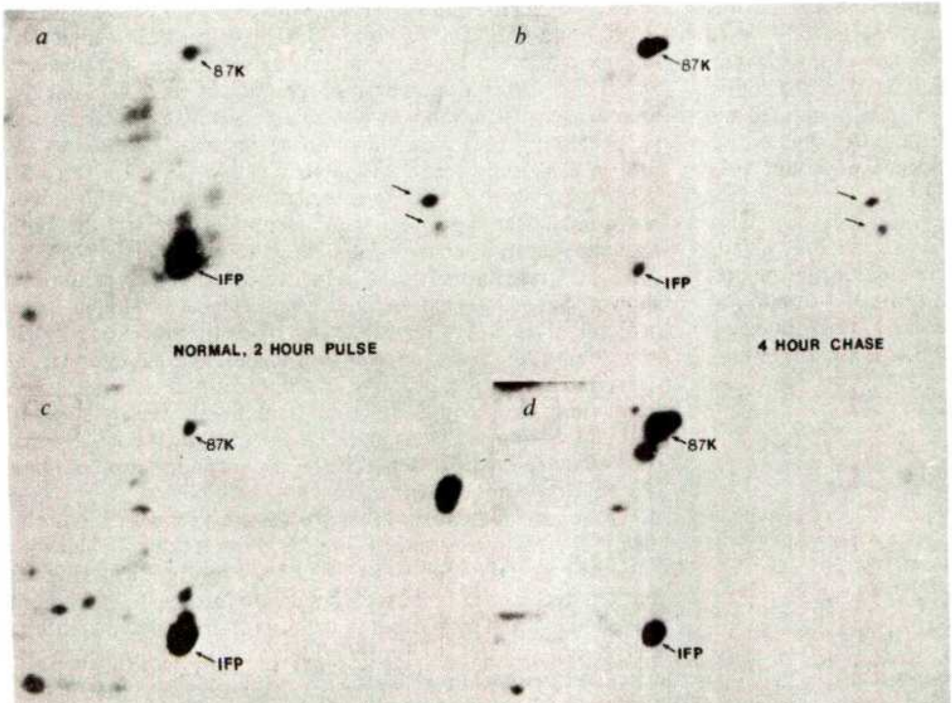

Fig. 2 Relatively slow turnover of phosphate on the 57 K and 55 K proteins. Normal chick fibroblasts (*a*) or Rous sarcoma virus (Prague C strain)-transformed fibroblasts (*c*) were incubated with 1 mCi ^{32}P-P$_i$ in phosphate-free medium for 2 h. The cells were prepared directly for two-dimensional gel analysis by lysis in 2.3% SDS containing 5% mercaptoethanol, heating at 95 °C for 3 min, and adding 2 volumes of 'standard dilution buffer'[22]. Alternatively, following the 2-h pulse, the ^{32}P-labelled normal (*b*) or transformed (*d*) cultures were incubated for an additional 4 h in Dulbecco's MEM (Gibco H-21) with 5% calf serum and 10% tryptose phosphate broth. The samples were prepared as before and whole cell phosphoproteins analysed by two-dimensional gel electrophoresis. In this and following experiments, 10^6 acid-precipitable c.p.m. were loaded per gel. Autoradiography was for 24 h. The 2-h pulse resulted in significant labelling of the 57 K and 55 K proteins in normal cells (*a*, arrows). Although the 4-h chase resulted in loss of label from IFP and most other proteins except protein of molecular weight 87,000 in both normal and transformed cells, there was no significant decrease in label associated with these normal cell phosphoproteins (*b*, arrows) in four successive experiments.

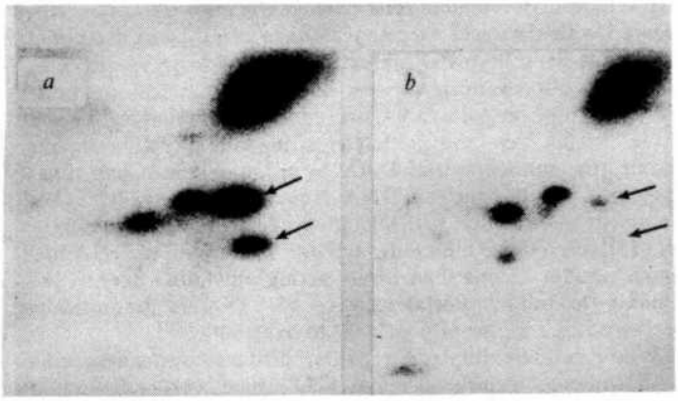

Fig. 3 Effect of growth temperature on phosphorylation of the 57 K and 55 K proteins in cells infected with the temperature-sensitive virus, tsNY68. Chick fibroblasts were infected with tsNY68 virus[19] and incubated at 41 °C (*a*) or 35 °C (*b*). Examination of the cultures by phase microscopy revealed normal cell morphology at a growth temperature of 41 °C (non-permissive temperature) and transformed morphology at a growth temperature of 35 °C (permissive temperature). Cultures at both temperatures were incubated with 1 mCi ^{32}P-P$_i$ per 60-mm plate for 2 h, then lysed in SDS and analysed by two-dimensional gel electrophoresis. Autoradiography was for 72 h. Labelling of the 57 K and 55 K phosphoproteins is seen to be heavy in cells grown at 41 °C, but is almost undetectable in cells grown at 35 °C. Temperature-shift experiments showed that detectable alterations in the phosphorylation state of these proteins occurred within 3–4 h of the temperature change. The two labelled spots seen to the left of the 57 K protein are normal cell phosphoproteins not seen in Figs 2 and 4 because of shorter exposure times.

phosphoproteins in the pulsed and chased transformed cells behaved in a similar fashion to that seen in normal cells.

It was important to determine whether dephosphorylation of the 57 K and 55 K proteins occurred in cells transformed by a temperature-sensitive mutant of Rous sarcoma virus (tsNY68). These cells manifest normal phenotype when maintained at a growth temperature of 41 °C, but show rapid and reversible morphological and biochemical transformation (within 6 h) when shifted to 35 °C (ref. 19).

We found a significant alteration in phosphorylation state of the 57 K and 55 K proteins when comparing cells grown at 41 °C (Fig. 3*a*) with cells grown at 35 °C (Fig. 3*b*). This phosphorylation state is temperature sensitive in both directions within 3–5 h of a shift in temperature, increasing when the temperature is raised and decreasing when the temperature is lowered (data not shown). Thus, it would seem that the dephosphorylation of these proteins is temporally linked to the onset of the transformed phenotype. The slow turnover of the phosphate on these proteins in normal cells (Fig. 2) when considered with these latter data, suggests the existence of a phosphatase activity in transformed cells that is specific for these phosphoproteins. Protein turnover as a significant factor in the dephosphorylation seems less likely, as ^{35}S-incorporation did not show a dramatic decrease in transformed cells and might simply result from some increased susceptibility of the dephosphorylated proteins to degradation.

We considered the possible existence of a specific phosphatase in a mixing experiment. Normal CEF or RSV-CEF were incubated with ^{32}P-P$_i$ and disrupted by nitrogen cavitation. These homogenates were incubated, either mixed (Fig. 4*c*, *d*) or unmixed (Fig. 4*a*, *b*), at 41 °C for 4 h. The phosphoproteins were analysed by two-dimensional gel analysis and autoradiography.

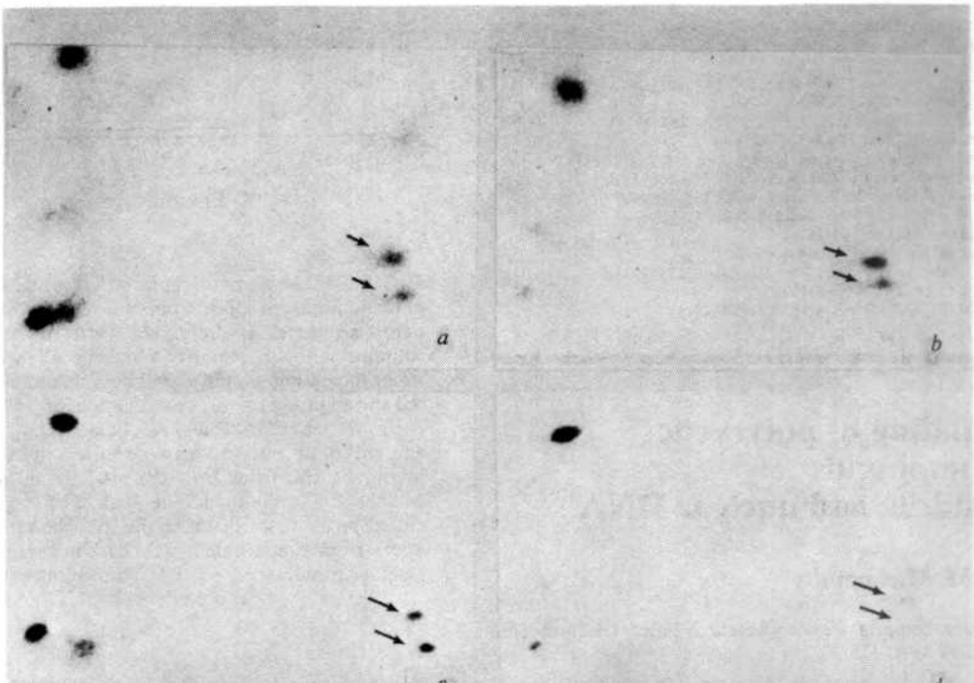

Fig. 4 Specific dephosphorylation of 57 K and 55 K phosphoproteins from normal cells by transformed CEF homogenate. Normal CEF were labelled with ^{32}P-P$_i$ (1 mCi per 100-mm plate) for 2 h and disrupted by nitrogen cavitation (400 p.s.i. in a Yeda cell press) in Tris-Cl buffered saline, *p*H 8.0. Phase microscopic examination of the homogenate showed that fewer than 5% of the cells remained intact. Unlabelled normal cells were also disrupted in the same fashion and mixed with the homogenate derived from an equal number of the labelled cells. An aliquot of this suspension was prepared immediately for electrophoresis (*a*) while the remainder was incubated at 41 °C for 4 h at which time another aliquot was prepared for electrophoresis (*b*). No significant decrease is seen in the level of label in the 57 K and 55 K phosphoproteins although IFP and most other phosphoproteins show marked loss of isotope. The 87 K phosphoprotein is apparently stable to phosphate loss. RSV-transformed (Prague C strain) fibroblasts were disrupted by the same protocol and mixed with the homogenate from an equal number of disrupted ^{32}P-labelled normal CEF. This suspension of mixed homogenates was either prepared for electrophoresis immediately (*c*) or incubated at 41 °C for 4 h (*d*) before SDS solubilization. All samples were analysed by two-dimensional gel electrophoresis. Autoradiography was for 24 h. It is apparent that mixing of transformed cell homogenate with ^{32}P-labelled normal cell homogenate results in the specific dephosphorylation of the 57 K and 55 K phosphoproteins. Note that no decrease in label associated with the 87 K phosphoprotein is detectable in the mixed homogenates (*c* and *d*). These results were verified in three successive experiments.

Only in the mixed homogenate was specific decrease in the activity of these proteins seen (Fig. 4*c*, *d*). The remainder of the autoradiographic pattern obtained with the mixed homogenate was identical to that found with unmixed homogenates. The protein patterns as detected by staining with Coomassie blue remained unchanged in all cases during the 4-h incubation suggesting that general protease activity was not important in these changes.

Our results suggest the presence of a phosphatase activity in transformed cells which appears specific for the 57 K and 55 K phosphoproteins. The function of the 57 K and 55 K proteins is presently unknown although both are membrane associated. The nature of the putative specific phosphatase activity is uncertain although several possibilities come to mind. It is possible that the *src* protein may activate a phosphatase specific for the 57 K and 55 K phosphoproteins. On the other hand, the *src* protein itself may contain an as yet unidentified phosphatase activity.

Covalent binding of polycyclic aromatic compounds to mitochondrial and nuclear DNA

J. A. Allen* & M. M. Coombs

Chemistry Laboratory, Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, UK

Since the pioneering work of the Millers[1] it has become clear that most chemical carcinogens require metabolism to reactive electrophiles and then exhibit their carcinogenic potential by reacting chemically with, and modifying, cellular macromolecules. At first modification of proteins was considered most likely to be of importance in carcinogenesis. Later, Brookes and Lawley[2] demonstrated that the extent of binding of several polycyclic hydrocarbons to DNA, but not to RNA or protein isolated from the skin of mice treated topically with these compounds, correlated with their known carcinogenic potency to this tissue. Mammalian cells, particularly mouse embryo cells, treated with chemical carcinogens have often been used, and DNA has been involved almost exclusively from whole cells. However, mitochondria possess unique DNA which accounts for 0.1–1% of the total DNA present in mammalian cells[3], and three studies have shown that carcinogenic alkylating agents modify the mitochondrial DNA by a factor about five times greater than the nuclear DNA from the same cells[4–6]. We demonstrate here that with six polycyclic aromatic compounds, all of which require metabolic activation and bind to DNA to a much smaller extent than direct-acting alkylating agents, the binding to mitochondrial relative to DNA is dramatically increased by a factor of nearly 50 to over 500.

Whole mouse embryo cells in their third passage from specific pathogen-free Tyler's Original (TO) mice were labelled in culture with [2-^{14}C]thymidine (60 mCi mmol^{-1}) and grown to confluency. Tritium-labelled polycyclic compounds (0.16–1.25 μg ml^{-1}, depending on toxicity) were added as shown in Table 1 and 24–48 h later the cells were collected, washed, and gently disrupted mechanically by hand using a Potter-Elvehjem homogenizer. Nuclei and mitochondria were isolated by the methods of Prescott *et al.*[7] and Miyaki *et al.*[8], respectively, and their purity was checked by light and electron microscopy. Nuclear DNA was extracted using Diamond's modification of the Kirby method[9] which involves isolation of the DNA from SDS lysates by phenol extraction, subsequent treatment with RNase, and a second isolation by phenol extraction. Mitochondrial DNA was obtained basically by the method of Hirt[10]; because mitochondrial DNA was lost during phenol extraction, the latter step and RNase treatment were omitted. The resultant solution of mitochondrial DNA therefore still contained mitochondrial RNA and residual protein which were also labelled

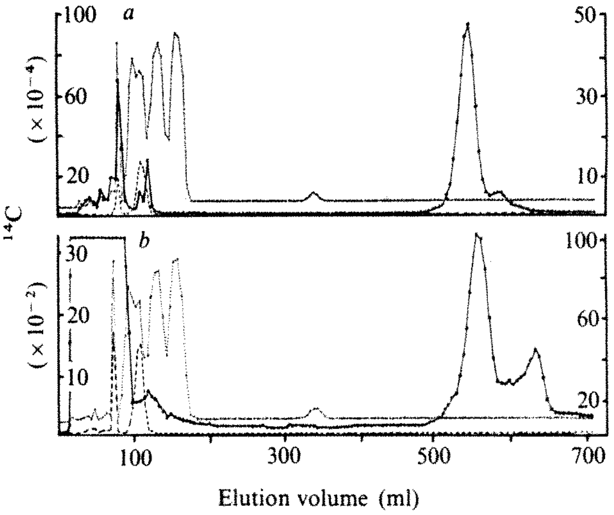

Fig. 1 LH20 chromatography of hydrolysates of nuclear (*a*) and mitochondrial (*b*) DNA from mouse cells treated in culture with benzo[*a*]pyrene. Hydrolysates were run on Sephadex LH20 columns of 90 × 1.5 cm with a linear gradient of 30% methanol in water increasing to 100% methanol. Fractions (5 ml) were collected and aliquots (1.5 ml) were counted for ^{14}C and ^{3}H activities in a LKB Wallac 1215 Rackbeta liquid scintillation counter. The amounts of the nucleosides were corrected for the efficiency of the hydrolysis, calculated from the total ^{14}C in the DNA hydrolysed and the ^{14}C in the thymidine peak. The large amount of tritium eluted in the first 100 ml of the mitochondrial DNA hydolysate arises from the tritiated hydrocarbon bound to the RNA and residual protein. ······, UV absorption at 254 nm; ●—●—●, ^{3}H d.p.m.; – – – –, ^{14}C d.p.m.

† Single experiment.

with tritium through binding to the hydrocarbons to these macromolecules.

The amount of nuclear DNA (usually 1–2 mg) was determined by UV spectrophotometry, having calibrated this by phosphorous analysis using the colorimetric method of King and Wotton[11]. Mitochondrial DNA was estimated, following enzymatic hydrolysis and separation of the deoxynucleosides, by relating the ^{14}C d.p.m. in the thymidine peak to the specific ^{14}C activity of the nuclear DNA, and was found to fall into the expected range (about 2 μg). On one occasion this was confirmed by direct estimation of the mitochondrial DNA by the fluorimetric micro method of Hill and Whatley[12] using mithramycin, thus establishing that the ^{14}C specific activities of the nuclear and mitochondrial DNA were similar. After dilution with carrier calf thymus DNA, both samples were hydrolysed enzymatically with DNase which had been carefully checked for absence of RNase activity, and the liberated deoxyribonucleosides were separated by Sephadex LH20 chromatography (Fig. 1). The binding index (μmol of compound bound per mol of DNA phosphorous) was calculated from the total amount of tritium in the modified deoxyribonucleoside peaks which elute after the natural deoxyribonucleosides, assuming the specific activity of the bound compound was unaltered. As Phillips *et al.*[13] have shown, residual protein and RNA do not interfere with this separation because they are eluted in the first 100 ml, immediately before the natural nucleosides. Six polycyclic aromatic compounds were examined in this way, the results of which are summarized in Table 1.

All six compounds modified both nuclear and mitochondrial DNA, and in each case the binding index for the latter was considerably higher than for the former. Although experimental difficulties made the precision of the values rather uncertain, the large differences observed cannot be explained by the small deviations in purine and pyrimidine base ratios known to exist between mammalian nuclear and mitochondrial DNA. These differences in binding index may occur because both the mitochondrial inner[14] and outer[15] membranes contain the enzymes required to metabolize polycyclic aromatic compounds which probably tend to accumulate in these lipophilic membranes[16]. Furthermore, mitochondrial DNA is 'naked', being devoid of the histone and non-histone proteins that are intimately associated with DNA in the nucleus. The highest DNA-binding indices, both nuclear and mitochondrial, are shown by the two most potent carcinogens: 7,12-dimethylbenz[*a*]anthracene (DMBA) and 3-methylcholanthrene (MCA). Benzo[*a*]pyrene and 15,16-dihydro-11-methylcyclopenta[*a*]phenanthren-17-one(11-MeCPP) are similar to each other in potencies[17], but are less active as carcinogens than DMBA and MCA; benz[*a*]anthracene is an extremely weak carcinogen whereas 12-MeCPP is inactive[18]. The nuclear DNA-binding indices of these last four compounds do not reflect this, whereas there is good correspondence with the mitochondrial binding indices. In all cases, the nucleoside adducts seen in the nuclear DNA hydrolysates are also present in the hydrolysates of the mitochondrial DNA, but in addition the latter also exhibit substantial amounts of slower-running adducts. In the case of benzo[*a*]pyrene[19] (shown in Fig. 1) and 11-MeCPP[20], the major nuclear adduct peak is known to represent the compound formed by reaction of the bay-region dihydrodiol epoxide with deoxyguanosine. The slower-running, less polar adducts therefore probably result from reaction of simple non-hydroxylated epoxides, such as K-region or non-K-region epoxides, with a DNA base.

The significance of these findings is not clear. As these cells contain about 1,000 times more nuclear than mitochondrial DNA, the actual amount of compound bound to the former is 2–20 times that bound to the latter. This does not imply that damage caused by this modification will also be in this ratio, because the efficiency of DNA repair may be different at these two sites. However, mitochondrial DNA codes for several essential subunits of ATPase, cytochrome bc_1 and cytochrome *c* oxidase[21], and it is therefore interesting that derangements of energy metabolism often characterize tumours (see ref. 22). Recently Wilkie *et al.*[23] found that most carcinogens they tested caused the cytoplasmic 'petite' mutation in the yeast *Saccharomyces cerevisiae*. Moreover, effects on the cell surface were observed in non-fermentable conditions where mitochondrial function is required for growth. These authors suggest a possible role for mitochondrial mutations in cancer through a heritable disturbance either directly or by modulation of a nuclear gene.

Early capping of transcripts from the adenovirus major late transcription unit

A. Babich, J. R. Nevins & J. E. Darnell Jr

The Rockefeller University, New York, New York 10021

The various events which result in modification of a primary RNA transcript may have a role in choosing transcripts which are to be processed into mRNA. If there is a stepwise and interdependent nature to each of the modifications then it is important to place the various steps in temporal order. We show here that the formation of a capped 5' terminus seems to be a very early event for adenovirus type 2 (Ad-2) nuclear RNA that is initiated at the major late Ad-2 promoter[1-5]. There is an equally rapid entry of ^{3}H-adenosine into the cap and the first dozen or so adenylate residues in the RNA chain. Taken together with evidence on general mRNA metabolism in Chinese hamster cells[6], it seems unlikely that capping has any differential role in successful RNA processing but rather is an automatic event for all RNA polymerase II products.

Location of the apparent initiation site for the major late adenovirus transcription unit near map position 16 on the genome (refs 3–5); 1 unit = 360 bases; 0 is at the 3' end of the rightward-transcribed strand) followed by the determination of DNA base sequence in this region[7-9] showed that the common late 5' mRNA sequence m^{7}GpppACUCUUCUG occurs only once near position 16 (refs 7–9). It therefore seemed likely that the initiating nucleotide in the primary transcript is the nucleotide which becomes capped during RNA processing. The viral DNA between 16.45 and 18.2 map units contains 536 bases of which 94 are thymidylate residues that are transcribed into adenylate residues in the primary RNA transcript as transcription proceeds from position 16.45 to position 18.2 (ref. 7). Together with the sequence information, an assay of chain length and a measurement of ^{3}H-adenosine in the labelled chains and in the cap, the frequency of capping as a function of chain size can be estimated. For instance, an RNA chain 32 nucleotides long would contain four AMP residues one of which would be in the cap; therefore, 25% of the radioactivity in such a molecule labelled with ^{3}H-adenosine would be in the cap.

Late in adenovirus infection, cells were labelled with ^{3}H-adenosine for 20 min and the total nuclear RNA that sedimented more slowly than 18S was hybridized to *Sma*F DNA (11.6–18.2 map units) that was immobilized on nitrocellulose filters. The hybridized RNA remaining after T1 RNase digestion was then eluted from the DNA. In the first experiment (Fig. 1) the presence of caps in the *Sma*F-specific RNA was determined by digesting the RNA to completion with RNases A and T2 and P$_1$ nuclease followed by treatment with bacterial alkaline phosphatase to release labelled adenosine residues from internal positions in the RNA chain and labelled nuclease-resistant 'cap core' structures[1,6]. Guanosine residues should also be labelled to the extent that ^{3}H-adenosine is converted to guanylate nucleotides. After electrophoresis of the digest (*p*H 3.5) the majority of radioactivity was represented by adenosine (Fig. 1), with also a small amount of guanosine. In addition, there was a peak of labelled, negatively charged material (fractions 38, 39, Fig. 1) that was resistant to the nuclease digestion and that migrated similarly to the appropriate cap core marker (m^{7}GpppAm).

About 2.7% of the total ^{3}H-adenosine radioactivity was in the form of the presumed cap structures (Table 1), suggesting a chain length of about 175 nucleotides if every chain were capped. As the size of the short promoter-proximal chains that were analysed was about 200 nucleotides (see Fig. 2*a*), it seemed that most of the chains must be capped. Because at least some of these molecules represent prematurely terminated transcripts[10,11], these results would indicate that the presence of a cap on an RNA transcript is not sufficient to ensure the completion of the chain.

It remained possible that some of the smallest promoter-proximal chains might be uncapped and contain pppA termini. Therefore the small RNA chains less than 18S were refractionated by sedimentation for a longer time through a second sucrose gradient (Fig. 2*a*). The peak of *Sma*F-specific RNA was in chains about 100–200 nucleotides long with significant hybridizable RNA both larger and smaller than tRNA (80 nucleotides). A 'large pool' from this gradient (fractions 2–7) represented chains longer than about 100 nucleotides, and a 'small pool' (fractions 8–12) contained molecules less than 100 nucleotides long. The promoter-proximal RNA was selected from both the large and small RNA pools by hybridization to the *Sma*F fragment. To detect potential uncapped termini that retained terminal phosphates, the nucleotide analyses were performed differently from those in the first experiment. After selection by hybridization, the RNA was digested only with P$_1$ nuclease and not with bacterial alkaline phosphatase so as to liberate labelled internal A or G residues as 5' nucleotides and leave 5'-terminal adenylate residues intact as either cap structures or uncapped polyphosphate residues[1,6]. After DEAE-paper electrophoresis (*p*H 3.5), both large and small RNA samples yielded pA and pG residues along with material migrating similarly to the cap core marker and the ADP marker (peak C, Fig. 2*b*, *c*). In addition there were two minor peaks (A and B, Fig. 2*b*,*c*) of P$_1$-resistant material that were completely resistant to further digestion by alkaline phosphatase and therefore did not contain terminal phosphates (data not shown).

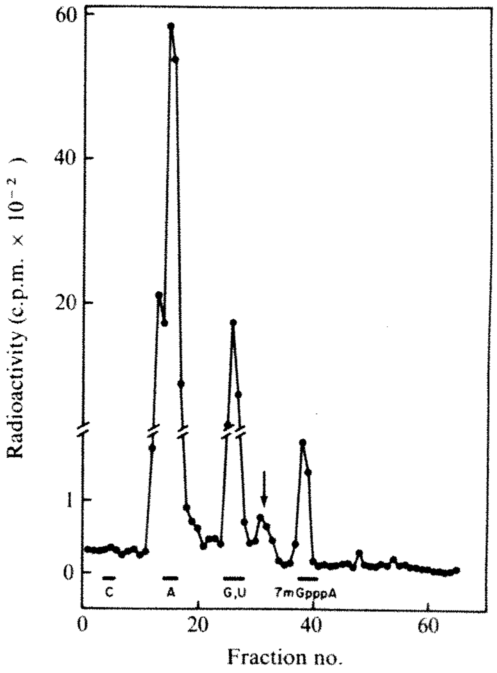

Fig. 1 Analysis of late Ad-2 promoter-proximal RNA for cap content. Adenovirus-infected cells at 16 h post-infection were labelled for 20 min with ^{3}H-adenosine (300 μCi ml^{-1}). The nuclear RNA was prepared and molecules of less than 2,000 nucleotides were isolated by sucrose gradient sedimentation. The promoter-proximal RNA was selected by hybridization to filter-bound *Sma*F DNA (map coordinate 11.6–18.2). After removal of unhybridized RNA and tails by digestion with T1 RNase, the filter was washed with 2 × SSC and then incubated with iodoacetate to inactivate the RNase. The RNA was eluted in H_2O by heating to 100 °C for 2 min. The RNA was first digested with RNase A (200 units ml^{-1}) and T2 (20 units ml^{-1}), followed by digestion with P$_1$ nuclease (200 units ml^{-1}) and then bacterial alkaline phosphatase (20 units ml^{-1}). The digest was analysed by electrophoresis on Whatman 3MM paper at *p*H 3.5. The arrow indicates the origin. The positive electrode is to the right.

0028–0836/80/380246—03$01.00

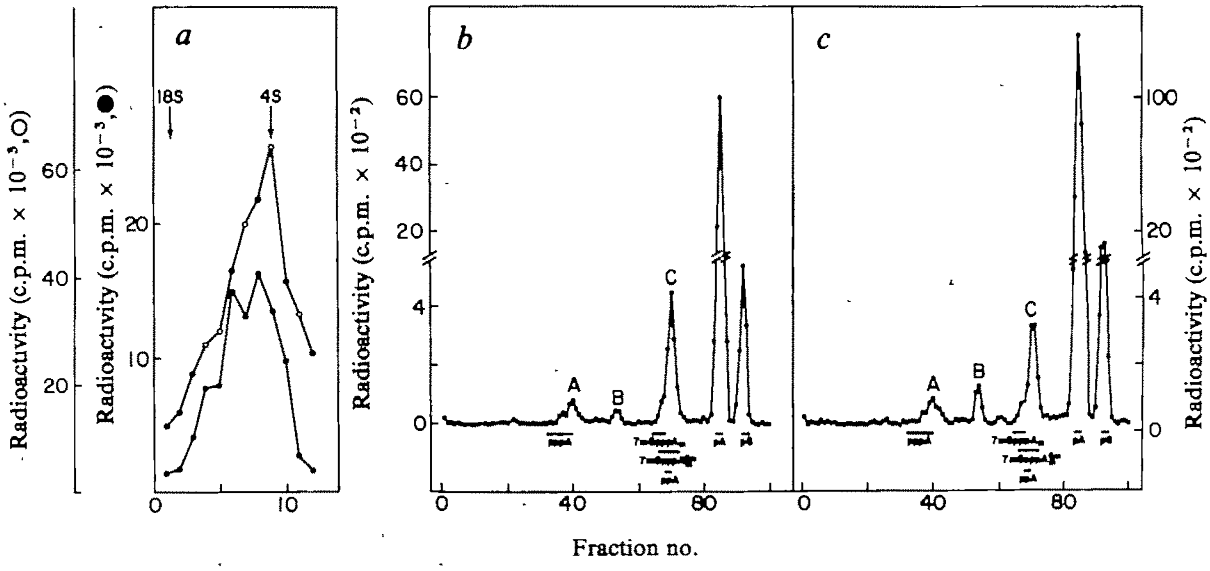

Fig. 2 *a*, Sedimentation profile of small, promoter-proximal late adenovirus nuclear RNA. RNA prepared from infected cells as described in the legend to Fig. 1 was resedimented in a second sucrose gradient (15–30% sucrose, SW41 rotor) at 30,000 r.p.m. for 19 h at 22 °C. Fractions of 1 ml were collected. Aliquots (10 µ1) of each fraction was counted directly in a Triton–toluene scintillant (○) and 50 µl of each fraction was assayed by hybridization to nitrocellulose filters containing the *Sma*F fragment (●). Two pools were made for subsequent analysis. A pool representing large RNA included fractions 2–7; a small RNA pool included fractions 8–12. Analysis of large (*b*) and small (*c*) promoter-proximal RNAs for 5′ termini. The two pools of RNA prepared as described in the legend to Fig. 2 were ethanol-precipitated and then each RNA sample was hybridized to filters containing the *Sma*F fragment. The eluted RNA was digested with P_1 nuclease (200 units ml^{-1}) and then electrophoresed on DEAE-paper at *p*H 3.5. Half of each lane was cut into 0.5-cm wide strips and counted. The other half was eluted and further analysed as described in Fig. 3 legend. The origin is at fraction 0 with electrophoresis towards the positive electrode.

Rather, this material could represent either ring-opened cap structures[12] or an incomplete P_1 digestion product. The major P_1-resistant material (peak C, Fig. 2*b*, *c*), which constituted 70–80% of the non-pA radioactivity, migrated during electrophoresis on DEAE paper as either a cap core (m^{7}GpppAm) or ADP. Treatment of this peak with alkaline phosphatase alone showed that the peak C material from both the large and small pools was resistant to alkaline phosphatase digestion and migrated with the cap core marker (Fig. 3*b*, *d*). The material from peak C was, however, sensitive to a combined pyrophosphatase and alkaline phosphatase digestion yielding labelled adenosine (Fig. 3*a*, *c*), confirming that it was in fact cap core. Thus there was no evidence for terminal phosphorylated structures even in the smallest RNA chains.

Again, in this experiment, the proportion of the radioactivity in caps compared with that in adenylate residues in the RNA chains indicated that all chains were capped. There was a ratio of one A in the cap per 30 As in the chain (or about 160 total residues) for RNA molecules from the larger pool and 1 in 12 (or about 70 total residues) for the smaller pool (Table 1). These estimates of chain length of capped molecules are in good agreement with the sedimentation sizes of the two RNA pools, indicating that nearly every chain possesses a cap, including those transcripts which average only 70 nucleotides and therefore must include many chains considerably shorter than 70 bases. Furthermore, no evidence of uncapped phosphorylated termini could be found even in the short chains. It should be pointed out that free pppA and pppG termini are readily detected in short cellular RNA transcripts that are presumably polymerase I and polymerase III products[6].

A previous analysis of the prematurely terminated transcripts from the major late adenovirus transcription unit demonstrated that in steady-state labelling conditions a prominent species of promoter-proximal RNA of chain length 200–250 nucleotides was detected[11]. Very few prematurely terminated RNA chains in the size range of 80–200 nucleotides were observed. This is not the situation for the promoter-proximal RNA prepared from cells labelled for 20 min with ^{3}H-adenosine where there are many chains in the size range of 100–200 nucleotides. Thus, it is likely that the chains which are less than 100 nucleotides long represent to some considerable degree, growing chains.

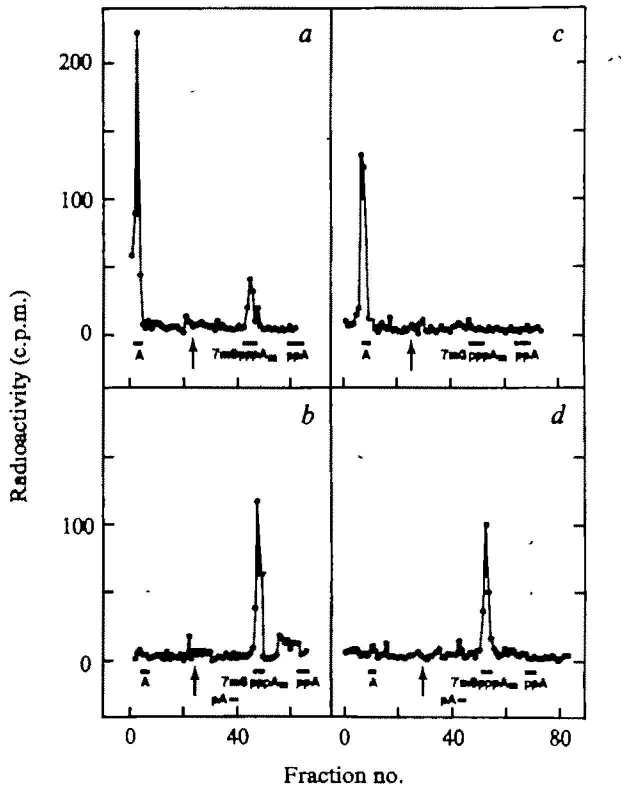

Fig. 3 Analysis of 5′-terminal structures from large and small promoter-proximal RNAs. The material designated as peak C in Fig. 2*b* and *c* was eluted from the DEAE paper in 30% triethylammonium carbonate, *p*H 7.4. The eluted material was lyophilized, dissolved in H_2O and then lyophilized again. The large RNA (*a*, *b*) and the small RNA (*c*, *d*) samples were divided into two parts. One part of each sample was digested with alkaline phosphatase alone. The other part was first digested with pyrophosphatase (1.5 units ml^{-1}) and then with alkaline phosphatase. The digestion products of each sample were then separated by electrophoresis on Whatman 3MM paper at *p*H 3.5. Strips 0.5 cm wide were counted. *a*, *c*, Pyrophosphatase plus alkaline phosphatase. *b*, *d*, Alkaline phosphatase alone. The arrow indicates the origin.

Table 1 Distribution of ^{3}H-adenosine label added late in adenovirus infection

Expt	RNA pool	Radioactivity (c.p.m.) As adenosine	As pA	As cap	% Radio-activity as cap	Predicted chain length
1	—	16,801	—	468	2.7	175
2	Large	—	27,591	978	3.4	153
	Small	—	11,061	1,085	8.9	70

The values for expt 1 are from the data presented in Fig. 1, and for expt 2 from the data presented in Fig. 2*b*, *c*. The predicted chain lengths are based on the location of thymidylate residues in the sequence of Ad-2 DNA between the start site for late transcription at 16.45 map units and the *Sma*I cleavage site at 18.2 map units[7]. For each RNA chain, the cap produced by RNase A and T2 digestion would contain one A residue.

Since these short chains had the highest cap content and did not reveal any pppA termini it is clear that capping occurs soon after synthesis is initiated. Our experiments cannot determine whether the 5′ terminus is capped concomitantly with the initiation of synthesis, although this is a possibility. Furuichi[13] has demonstrated that the formation of a capped 5′ terminus on the cytoplasmic polyhedrosis virus mRNA is a pre-transcriptional event. Weil *et al.*[14] also showed that correct initiation of Ad-2 transcription can be obtained *in vitro* by RNA polymerase II in the presence of a crude cell extract. This crude *in vitro* system produces chains with capped ends. In addition to Ad-2 transcripts, polymerase II cellular transcripts also have caps added early during synthesis[6]. Thus an association of capping enzymes with the initiation complexes for polymerase II transcription is a distinct possibility.

The Archaebacteria and eukaryotic origins

Leigh M. Van Valen & Virginia C. Maiorana

Biology Dept (Whitman), University of Chicago, 915 E. 57th Street, Chicago, Illinois 60637

Critical analysis of the phylogeny of prokaryotes is in its infancy. Woese and others[1–5] have made the startling proposal that methane-producing bacteria and a few others form a phyletically unified group, the Archaebacteria, as old and as diverse (although not now as numerous) as all other bacteria. The only critique[6] of this proposal is inadequate[7]. Here we present an alternative view, that the Archaebacteria were derived from other bacteria and contain the ancestor of a cell which engulfed others, eventually to become the first eukaryote.

The main evidence used for the relative time of divergence of the Archaebacteria is that their 16S ribosomal RNA is very different from that of other bacteria. However, as Woese recognizes[3], this can be the result of rapid early evolution. The origin of new adaptations often occurs rapidly, as exemplified by the evolution of bats[8], whales[9] and modern placental mammals as a whole[10]. Evolutionary rates vary widely[11], and an attempt[12] to extrapolate the average rate of evolution of cytochrome *c* from vertebrates to angiosperms gave results which contradicted the fossil record[13]. (We do not mean to dispute the usual approximate constancy of protein evolution.) Proteins themselves often evolve unusually rapidly when they undergo a major change in function[14,15]. Even the supposedly nearly invariant histone H4 is very different between ciliates and other eukaryotes[16]. The suggestion[5] that the diversity of Archaebacteria argues against rapid evolution near their origin is a non sequitur; placental mammals are a familiar counter-example in which both phenomena occur. The only studied genomes of archaebacteria are small[17,18], although far from the smallest known for prokaryotes[19].

Our proposal (Fig. 1), based in part on work by Margulis[20], Hall[21] and others, takes the evolution of mechanisms for acquisition of free energy to be central. We discuss the general topic elsewhere[22]. Any phylogeny must be based on a clear recognition of primitive states and derived states, for shared primitive states give no phyletic information[23,24]. A set of differences is not in itself an adequate basis for a phylogeny, in part because the base of the phylogeny can then be anywhere. We take glycolysis alone (as in some lactic-acid bacteria), especially its later stages, to be primitive among surviving organisms because it is almost universally distributed and provides materials for other, presumably derived, processes such as the completed tricarboxylic–acid cycle.

The Archaebacteria are moderately derived prokaryotes in this view, although most surviving prokaryotes are even more derived. Why then should they be so divergent from the others? The answer may be lost in the Archaean, but we can offer an initial suggestion. One of the free-living Archaebacteria, *Thermoplasma*, lacks a cell wall, while the other known Archaebacteria have a wide diversity of cell walls[25] all very different in composition from the walls of all other walled cells. Thus it seems as though the ancestral lineage of Archaebacteria lost its cell wall, possibly for flexibility in locomotion or for energy conservation. Such a change could be related to other changes in adaptation.

Moreover, *Thermoplasma* itself shows several specific and derived similarities with eukaryotes[26]. It has a histone-like protein which produces nucleosome-like condensations of DNA. It has actin- and myosin-like proteins and microbody-like respiration. It can invaginate its plasma membrane, although apparently not with fully developed endocytosis. Such an ability is necessary for a cell which engulfs others.

However, like other surviving Archaebacteria[27], *Thermoplasma* has lipids with branched chains and with ether linkages instead of the esterifications of other prokaryotes and eukaryotes[28]. Unless eukaryote lipids came from another member of the presumptive symbiosis, this suggests that the surviving Archaebacteria evolved their unique lipids and other traits after the ancestral eukaryote diverged.

Halobacterium, a surviving archaebacterium[29] with independently derived light-driven ATP synthesis[18,30], has other specific and derived similarities with eukaryotes. Its light-transducing pigment is almost identical to rhodopsin[18]. Its initiator tRNA resembles that of eukaryotes in some ways[18] and produces a non-formylated methionine[18], as in eukaryotes. The only ribosomal protein studied has a partial amino acid sequence nearly intermediate between those of the bacterium *Escherichia* and the yeast *Saccharomyces*[18]. *Halobacterium* has a ferredoxin rather similar to that of plants[18], and its cell wall is composed of a glycoprotein resembling those of eukaryotic cell walls[18]. It even seems to have more than one non-plasmid chromosome, perhaps several[18]. Another archaebacterium,

primordial cells

Fig. 1 Provisional phylogeny of prokaryotes.

Methanobacterium[17], but not *Halobacterium*[18], may have some repeated DNA.

Perhaps those resemblances to eukaryotes (except probably the cell wall) and those of *Thermoplasma* were present together in an ancestral form (*Thermoplasma* has not been studied for all of these characters) and some have been modified in each lineage. All enzymes of the tricarboxylic-acid cycle occur in archaebacteria, but not all together in the same species[5]. Parasitic mycoplasms also show some specific resemblances to *Thermoplasma*[25,31]; their relation to Archaebacteria needs clarification.

We therefore provisionally regard the Archaebacteria as one of several phyla of prokaryotes, most as yet undefined. The Proalgae (new name) are another, comprising the Cyanophyta and Prochlorophyta[32]—the oxygen-releasing prokaryotic algae. (Eukaryotic algae, not a natural group, can be called eualgae, a term which makes adjectives easily. Proalgae are true algae adaptively; to call them bacteria[33] is like calling mammals and birds reptiles[34] because both groups come from the evolutionary radiation of reptiles.)

How can we test such hypotheses? One way is to investigate further the extent to which the proposed phylogeny, and any alternatives, make adaptive sense, using as many characters as possible. A second, more decisive when it can be applied, is to accumulate characters from which the topology of evolutionary relationships can be inferred, whenever possible with information on what state is primitive and with recognition of the possibility of convergence, especially by loss. Sequences of proteins and nucleic acids give the greatest density of such characters, but the data on rRNA (not sequences because only isolated oligonucleotides have been studied) suggest that so great changes may have occurred in the origins of both archaebacteria and eukaryotes that even such slowly evolving molecules show only random similarity to those of their ancestors. Primitive eukaryotes such as *Eimeria*[35] and *Pelomyxa*[36] also deserve intensive scrutiny.

The translation apparatus of Archaebacteria differs from that of other organisms[4]. Perhaps there is an unbridgeable adaptive valley in this difference[3]. However, we think that this matter cannot be discussed adequately until much more is known about the functioning of existing translation apparatuses, and of potential intermediates, in realistic conditions. Until then we prefer to emphasize other evidence; it is dangerous to claim something is impossible in biology. The same function can be performed very differently in different selective conditions[37].

Nevertheless, Fig. 1 is consistent with existing evidence from macromolecular sequences[38] if primitive aerobic photosynthesizers are now extinct. Reticulate evolution by gene transfer provides an available and plausible excuse for disparities such as the presence in *Halobacterium* of a normal complement of cytochromes in an electron-transport chain[30], but there is a surprising lack of compelling evidence for its importance in any real case.

Archaebacterial elongation factor is ADP-ribosylated by diphtheria toxin

Michael Kessel & Friedrich Klink

Biochemisches Institut, Universität Kiel, Olshausenstrasse 40–60,
D-2300 Kiel 1, FRG

Archaebacteria have been defined as a 'third primary kingdom' of cells in addition to the urkaryotes and the eubacteria[1]. While the latter two correspond approximately to the conventional categories eukaryotes and prokaryotes respectively, the Archaebacteria have up to now comprised four groups of microorganisms: the methanogenic bacteria, the extremely halophilic bacteria and the two thermoacidophilic genera *Sulfolobus* and *Thermoplasma*. Based on ribosomal RNA sequence homologies and lipid composition, they apparently form a distinct group. Furthermore they possess or lack typical biochemical markers of both the eukaryotes and the prokaryotes, as well as having unique properties not found elsewhere[2]. Altogether, this indicates that they are not closer to either one of the classical categories. One clear-cut difference between prokaryotes and eukaryotes is the diphtheria toxin reaction, which catalyses the covalent binding of adenosine diphosphate-ribose (ADPR) to the eukaryotic peptide elongation factor EF2 in contrast to the homologous prokaryotic factor EF-G[3,4]. We report here that diphtheria toxin also catalyses the ADP-ribosylation of archaebacterial elongation factors. In this respect, these factors have to be assigned to the EF2 type; we suppose that the ADP-ribosylatable structure arising so early in evolution is of fundamental importance for the elongation process.

We have investigated crude cytoplasmic fractions of four main representatives of the Archaebacteria: *Halobacterium cutirubrum*, *Methanobacterium thermoautotrophicum*, *Sulfolobus acidocaldarius* and *Thermoplasma acidophilum*. After reaction with diphtheria toxin fragment A and ^{14}C-NAD labelled in the adenine moiety only one protein received a label. This could be demonstrated as radioactivity precipitable by trichloroacetic acid (TCA) and as one radioactive band in SDS–gel electrophoresis (Fig. 1). While *M. thermoautotrophicum*, *S. acidocaldarius* and *T. acidophilum* required the normal conditions[3] for the toxin reaction (neutral *p*H, about 0.05 M K^+, 30 min, 37 °C), high salt (3.8 M K^+ or 2.6 M NH_4^+) and 4 h incubation time were necessary for the extremely halophilic extract to attain maximum labelling. This reflects that the halophilic protein could only react in its native, salt-stabilized conformation, while the toxin fragment A, which has been shown to be remarkably stable to heat[6], extreme *p*H[6] and proteolytic enzymes[4], also tolerates high salt.

For comparison, a number of elongation factors from various eukaryotic sources were ADP-ribosylated in the same manner as the archaebacterial proteins; they showed the same mobility in one electrophoresis system, indicating a molecular weight (M_r) of 96,000. Isotopically labelled proteins from *M. thermoautotrophicum*, *S. acidocaldarius* and *T. acidophilum* were considerably smaller with apparent M_r of 86,000 for *M. thermoautotrophicum* and 83,000 for both the thermoacidophiles. These values are in the range of the M_r reported for the prokarytic, non-ADP-ribosylatable homologue EF-G, which is about 80,000 (ref. 7). The M_r of 111,000 found for the halophilic protein is exceptionally high. The EF-Gs from *Escherichia coli*[8] and *Streptococcus faecalis*[9] as well as mitochondrial factors[10] were shown to be unable to react with NAD and diphtheria toxin. We confirmed this for *Pseudomonas maltophila*, *Bacillus licheniformis*, *E. coli* K 12, *Hyphomicrobium* 526 and *Pedomicrobium* S 122.

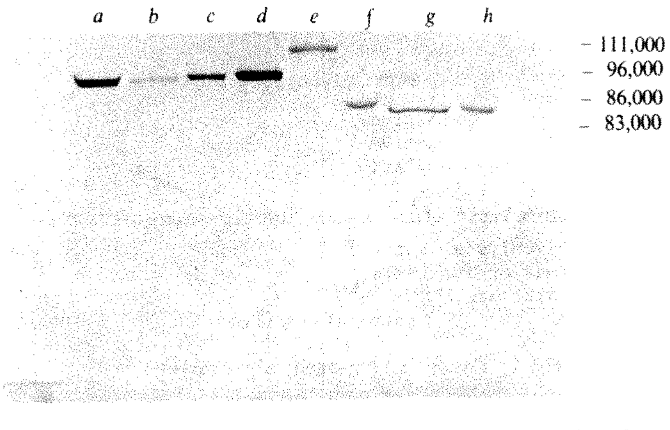

Fig. 1 Products of diphtheria toxin reaction from eukaryotic and archaebacterial sources. Crude fractions of soluble proteins were incubated with mercaptoethanol-reduced toxin (10–20 flocculation units per 75 μl), ^{14}C-NAD (10^{-6} M) and 0.05 M KCl for 30 min at 37 °C. Different conditions were used for the extreme halophile: saturated potassium chloride and incubation time of 4 hours. The reaction mixtures were separated on polyacrylamide gels (7.5%)[5], which were autoradiographed for 6 days. Calibration proteins were phosphorylase b (M_r 94,000), bovine serum albumin (M_r 67,000), catalase (M_r 58,000) and ovalbumin (M_r 43,000). The sources were as follows: *a*, wheat germ; *b*, rabbit liver; *c*, rat thymocytes; *d*, bovine liver; *e*, *H. cutirubrum*; *f*, *M. thermoautotrophicum*; *g*, *S. acidocaldarius*; *h*, *T. acidophilum*. Numbers on the right indicate M_r.

0028-0836/80/380250—02$01.00

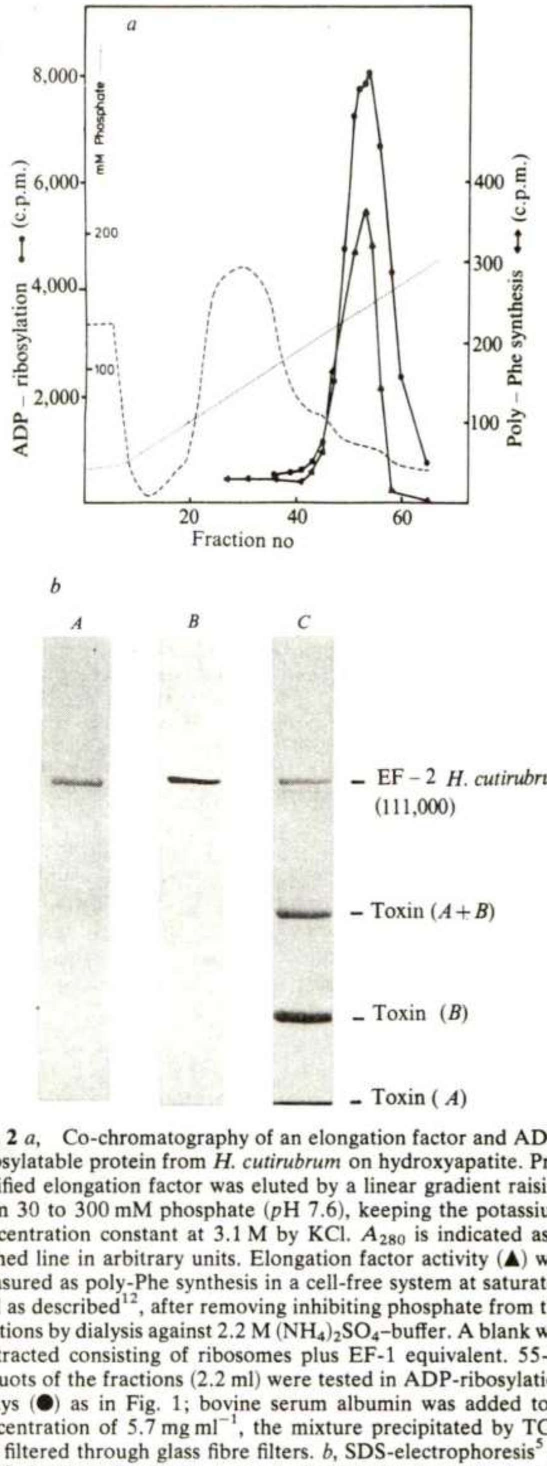

Fig. 2 *a*, Co-chromatography of an elongation factor and ADP-ribosylatable protein from *H. cutirubrum* on hydroxyapatite. Pre-purified elongation factor was eluted by a linear gradient raising from 30 to 300 mM phosphate (*p*H 7.6), keeping the potassium concentration constant at 3.1 M by KCl. A_{280} is indicated as a dashed line in arbitrary units. Elongation factor activity (▲) was measured as poly-Phe synthesis in a cell-free system at saturated KCl as described[12], after removing inhibiting phosphate from the fractions by dialysis against 2.2 M $(NH_4)_2SO_4$–buffer. A blank was subtracted consisting of ribosomes plus EF-1 equivalent. 55-μl aliquots of the fractions (2.2 ml) were tested in ADP-ribosylation assays (●) as in Fig. 1; bovine serum albumin was added to a concentration of 5.7 mg ml^{-1}, the mixture precipitated by TCA and filtered through glass fibre filters. *b*, SDS-electrophoresis[5] of purified elongation factor. Lane *A*, Coomassie blue stain; lane *B*, autoradiography of purified, ADP-ribosylated factor; lane *C*, Coomassie blue stain of lane *B*, containing the toxin bands.

Further investigation of the extremely halophilic archaebacterium *H. cutirubrum* identified the labelled protein with an elongation factor. For the protein synthesis test we modified a test system developed by Bayley[11], using poly(U) as a messenger, tRNA Phe as substrate and an EF-1-equivalent from *H. cutirubrum*[12], which complements with EF-2 to poly-Phe synthesis. The EF-2 co-purified with the ADP-ribosylatable protein using a three-step procedure on Sepharose with a decreasing $(NH_4)_2SO_4$ gradient, gel filtration at 0.9 M KCl/1.1 M $(NH_4)_2SO_4$ and hydroxyapatite (details to be reported elsewhere). The factor elutes from hydroxyapatite at 150 mM phosphate and is nearly homogeneous (Fig. 2*a*). The purified factor reacts with NAD and toxin as described for the crude fraction at high salt conditions. Under modified purification procedures we have also observed a main Coomassie blue band in SDS electrophoresis of M_r about 93,000 (ref. 12), probably due to proteolysis of the factor. The active, ADP-ribosylatable elongation factor from *H. cutirubrum* has a M_r of 111,000 in SDS-electrophoresis (Fig. 2*b*).

The structural basis of the diphtheria toxin reaction in eukaryotic systems is well established: the ADP-ribose residue of NAD is bound covalently to a post-translationally modified histidine[13] (previously called 'X', ref. 14), which only occurs in EF-2. The amino acid sequence of the ADP-ribosylation site has been shown to be highly conserved in yeast, wheat germ, rat and bovine liver[15]. It is obvious that the Archaebacteria also provide the prerequisites for the toxin reaction. Taking into account the high specificity of the toxin for EF-2 and also the evidence from the halophilic system, we conclude that the ADP-ribosylated protein in archaebacteria is an EF-2-type elongation factor. The eukaryotic feature of this elongation factor is a good argument for the separation of Archaebacteria from the prokaryotes as a 'third primary kingdom' (ref. 1). The evolutionary pressure also seems to have worked over the large phylogenetic distance from Archaebacteria to higher vertebrates. This consideration is further strengthened by results about ribosomal proteins, which are probably part of the binding site for the elongation factors on the ribosome[16]. These ribosomal A-proteins (L7/L12-equivalents) show a high degree of N-terminal sequence homology between halobacterial and eukaryotic systems[17]. Thus conservation of these cooperating structures may indicate functional importance for the elongation process in urkaryotes and their possible ancestors.

We thank R. Gehrmann, R. Gebers (Kiel) and K. O. Stetter (Munich) for gifts of bacteria or bacterial extracts, and E. Kaufmann for technical help. Diphtheria toxin was provided by Behring-Werke.

Biophotolytic H_2 production using alginate-immobilized chloroplasts, enzymes and synthetic catalysts

P. E. Gisby & D. O. Hall

University of London King's College, Department of Plant Sciences, 68 Half Moon Lane, London SE24 9JF, UK

Hydrogen can be produced by illumination of an aqueous mixture of chloroplasts and hydrogenase, in the presence of an electron carrier[1,2]. This system may have potential for development of a solar converter to produce hydrogen from water[3,4] if it can be stabilized or constructed as a completely synthetic system. The immobilization of the chloroplasts, or membrane analogues, would make possible a one-stage reactor with all the components in one chamber, or a two-stage reactor if the electron carrier was passed to another chamber to react with

an immobilized hydrogen-producing catalyst. However, techniques for immobilizing enzymes tend to yield immobilized chloroplasts that are not very active, and other methods must be used[5–8]. We describe here the immobilization of chloroplasts using calcium alginate gels on reinforcing grids of nylon and stainless steel. Chloroplasts thus immobilized are fully active and can be used to produce hydrogen gas. Strengthened films of this sort could provide a good, solid, rigid matrix for a solar converter.

Sodium alginate is a soluble polysaccharide, but calcium alginate is an insoluble gel. If a chloroplast suspension is mixed with a 1 or 2% sodium alginate solution and then brought into contact with 0.1 M calcium chloride, the calcium alginate gel forms immediately. Thus, if the mixture is dropped into calcium chloride from a syringe, the drops solidify on contact and form nearly spherical balls, with the chloroplasts immobilized inside. This approach was used successfully for the immobilization of microbial cells by Cheetham *et al.*[9]. The same method was used in our laboratory and the spheres were found to be active in the hydrogen production system[8] though they tended to disrupt after some time. Further experimentation showed that we could also make flat films of gel inside which the chloroplasts were entrapped; these proved to be much better than the spheres.

The films tended to be rather fragile, and broke up if stirred or shaken for more than 5 min; this problem was overcome by covering a solid grid support with the sodium alginate–chloroplast mixture and dropping calcium chloride on to this mixture with a pipette. The result is that the support becomes embedded in the calcium alginate, giving a flat, rigid structure. The principle is similar to that of reinforced concrete. Muslin was initially used as the strengthening grid but we have also tried nylon and stainless steel. Stainless steel has, in fact, proved to be the best so far, giving strong, easy-to-make films which do not fragment on shaking.

The photosynthetic activity of immobilized chloroplasts was assayed in an oxygen electrode and compared to that of free chloroplasts, using both potassium ferricyanide (oxygen evolution) and methyl viologen (oxygen uptake) as electron acceptors, as shown in Table 1. It was necessary to use only small amounts of chloroplasts for assay because the alginate film was such that it lined the inside of the electrode cavity and the buffer solutions flowed past it. As the illumination of the film was from one side only, that part of the film nearest the light shaded the rest of the film; this was considerable when 100 μg total chlorophyll was immobilized in the film. Stirring would have overcome this problem with free chloroplasts, but this was not possible with immobilized ones. Therefore, it was decided to decrease the amount of chlorophyll present so that the illumination should be saturating over the entire area of the film. Table 1 clearly shows that the photosynthetic electron transport activity of the film-immobilized chloroplasts was not diminished by the immobilization process compared to that of free chloroplasts. However, the spheres only showed 49% of the activity of free chloroplasts.

Table 1 Photosynthetic electron transport activity of immobilized and non-immobilized chloroplasts

	Free chloroplasts	Immobilized chloroplasts	
		Spheres	Films
O_2 evolution rate (μmol O_2 evolved per mg chlorophyll per h)	200	98	198
O_2 uptake rate (μmol taken up per mg chlorophyll per h)	207	107	205

Chloroplasts were isolated essentially as in ref. 13 and resuspended in a solution of 10 mM NaCl, 10 mM HEPES, *p*H 7.5 (2 mg chlorophyll ml^{-1}). Assays were carried out in a Rank oxygen electrode at 25 °C. The reaction mixture contained, in a final volume of 4 ml, chloroplasts containing 25 μg of chlorophyll, 50 mM HEPES, *p*H 7.5, and 10 mM NaCl. For O_2 evolution, the electron acceptor was potassium ferricyanide (3 mM). For O_2 uptake, the electron acceptor was methyl viologen (50 μM)[14]. Both O_2 evolution and uptake were measured in the presence of 2 μM carbonyl cyanide *p*-trifluoromethoxyphenol hydrazone, uncoupling agent. Alginate spheres were made by mixing chloroplasts containing 25 μg chlorophyll with 1 ml of a solution of 1% sodium alginate + 50 mM HEPES (*p*H 7.5) + 1% bovine serum albumin (BSA) and dropping this mixture into 100 ml of 0.1 M $CaCl_2$ + 50 mM HEPES (*p*H 7.5). The films were made by mixing chloroplasts containing 50 μg chlorophyll with 1% sodium alginate + 50 mM HEPES (*p*H 7.5) to final volume of 300 μl. A nylon grid, 1 × 2 cm, mesh 45, aperture size 0.32 mm, was covered in 150 μl of this mixture, and 3 ml of 0.1 M $CaCl_2$ + 50 mM HEPES (*p*H 7.5) were dropped onto the film with a pipette.

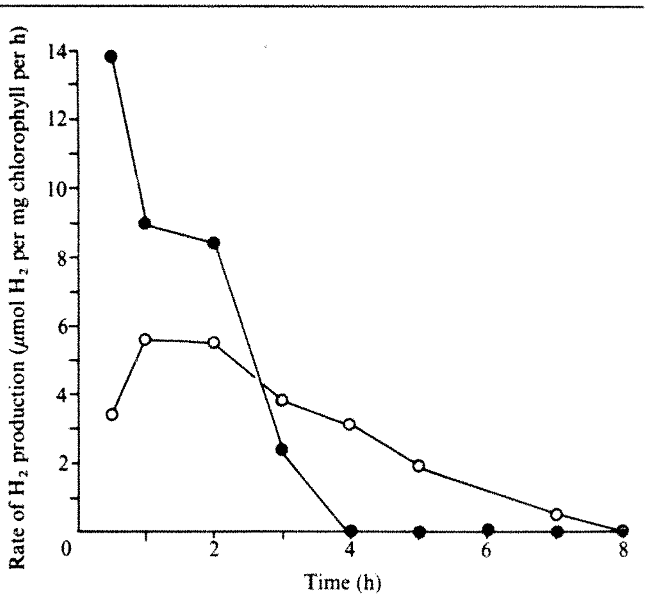

Fig. 1 Rate of hydrogen production against time for system (3)—platinum-polyvinyl alcohol and methyl viologen with spinach chloroplasts. Reaction conditions were as shown for system (3) in Table 2 legend. (Data are from a longevity experiment separate to those shown in Table 2.) ●, No components immobilized; ○, chloroplasts, electron carrier and H_2-evolving catalyst in alginate gel film. Oxygen trap present in both.

Next, we were interested to see if immobilized chloroplasts could be used to produce hydrogen gas, as can free chloroplasts[1,2] using hydrogen-producing catalysts and the appropriate electron carriers. Three catalytic systems were used: (1) *Clostridium pasteurianum* hydrogenase with *Spirulina maxima* ferredoxin as the electron carrier; (2) *Desulfovibrio desulfuricans* (strain Norway) hydrogenase with methyl viologen as electron carrier, and (3) a synthetic catalyst platinum-polyvinyl alcohol[10] with methyl viologen as carrier. The films were made by mixing double the required amount of chloroplasts, electron carrier and catalyst to a final volume of 150 μl. This was then mixed with 150 μl of a solution containing 4% sodium alginate (BDH batch 6097490), 1% bovine serum albumin and 50 mM HEPES, *p*H 7.5, giving a final sodium alginate concentration of 2%. A stainless steel grid (1 × 2 cm, 20 mesh, aperture size 0.99 mm) was covered with 150 μl of the final mixture and then 3 ml of solution containing 0.1 M $CaCl_2$ and 50 mM HEPES, *p*H 7.5, was dropped on to the film from an automatic pipette.

Table 2 shows that hydrogen-evolution was observed using the immobilized chloroplasts, with quite good rates in immobilized systems (1) and (3). However, the percentage of the same reaction system where none of the components are immobilized (figures in parentheses), shows that the rate retained by system (1) after immobilization is 24%, but that for system (3) is 67%. In an immobilized system we have never retained more than 25% of the maximum hydrogen-evolving activity attainable (that is system (1), non-immobilized).

At this stage, the important point is not the absolute rates of hydrogen production (as compared to free chloroplasts) but that the immobilized chloroplasts will evolve hydrogen at reasonable rates. Following work showing the generation of photovoltages and photocurrents[4], it was shown that immobilized chloroplasts and algal cells will produce photocurrents in a three-electrode system when they are coated on an electrode and a suitable potential applied[11]; however, these systems do not produce hydrogen. We have attempted to develop a catalytic solar energy converter which uses water as the source of electrons and protons, and which ultimately gives rise to hydrogen. The system described here is the only one known which fulfils these criteria.

Table 2 Rates of hydrogen production from immobilized and non-immobilized systems

	H_2 evolved (μmol per mg chlorophyll per h)		
	System (1): chloroplasts +*C. pasteurianum* hydrogenase +*S. maxima* ferredoxin	System (2): chloroplasts +*D. desulfuricans* hydrogenase +methyl viologen	System (3): chloroplasts +Pt.PVA +methyl viologen
No components immobilized	21.0 (100%)	7.1 (100%)	7.2 (100%)
Chloroplasts, electron carrier and H_2-evolving catalyst in alginate gel film	5.0 (24%)	1.1 (15%)	4.8 (67%)
No components immobilized, oxygen trap omitted	10.7 (51%)	2.8 (39%)	0 (0%)
Chloroplasts, electron carrier and H_2-evolving catalyst in alginate film, oxygen trap omitted	1.8 (9%)	0.2 (3%)	0 (0%)

Chloroplasts (type C)[15] were prepared essentially as described in ref. 13 and finally suspended in 10 mM NaCl, 10 mM HEPES, *p*H 7.5 (7.5 (2 mg chlorophyll ml^{-1}). Assays for H_2 evolution were carried out in 15-ml glass vials. The reaction mixture (final vol 2 ml in 50 mM HEPES, *p*H 7.5) contained 100 μg chlorophyll, 1% BSA (fraction V powder). When present, the oxygen trap consisted of 100 μmol of glucose, 10 units glucose oxidase, 1,000 units catalase and 20 μl ethanol. System (1) *C. pasteurianum* hydrogenase added to excess; *S. maxima* ferredoxin (25 nmol per vial). System (2) *D. desulfuricans* (strain Norway) hydrogenase, added to excess; methyl viologen was present at 50 μM. System (3) Pt. PVA = platinum-polyvinyl alcohol, containing the equivalent of 125 μg platinum per vial, methyl viologen 50 μM. Hydrogen evolution was assayed over 2 h at 11,000 l and 25 °C using a gas chromatograph as described in ref. 16. Alginate gels were made as described in the text.

The *in vitro* production of hydrogen from reduced substrates, for example EDTA and ascorbate, using dyes as mediators is well established, and efficiencies of 5% conversion of monochromatic light have been reported[4,12]. However, catalytic water-splitting systems have only been substantiated thus far using chloroplast membranes, where the lack of sustained and linear hydrogen production rates over many hours has not allowed the meaningful measurement of solar energy conversion efficiencies.

For the development of a large-scale solar converter, we are investigating the replacement of as many biological components as possible with synthetic compounds, largely because of the instability and expense of the former. System (3) of Table 2 is of particular interest in this respect because in it we have replaced the ferredoxin and hydrogenase used in system (1) with methyl viologen and platinum-polyvinyl alcohol, respectively. In Fig. 1 we show that if calcium alginate-immobilized chloroplasts are used with the two synthetic catalysts of system (3), although the initial rates are lower than for free chloroplasts, we increase the longevity of the system twofold. Preliminary work shows that the inorganic catalysts are not well retained in the gel after initial entrapment, as some leakage occurs. There is, however, no leakage at all of the chloroplasts themselves. Separate immobilization of the synthetic and biological catalysts, and their subsequent incorporation into the alginate gels, supported on a rigid matrix, is the next phase of our work.

We thank Dr K. K. Rao and Miss U. Schleicher for help and the Commission of the European Communities for support. P.E.G. is a British Gas Corporation scholar.

Note added in proof: Initial experiments with free chloroplasts, in collaboration with Dr A. Harriman, have given quantum efficiencies for hydrogen-producing systems (1), (2) and (3) of 0.126 (12.6%), 0.025 (2.5%) and 0.032 (3.2%), respectively (see Table 2).

Secondary isotope effects in studies using radiolabelled folate tracers

Michael J. Connor*, John A. Blair† & Hamid Said†

The use of isotopically labelled compounds as metabolic tracers in *in vivo* and *in vitro* studies is particularly important in folate biochemistry, where the natural coenzyme forms occur in transient and trace amounts. However, during our studies on the whole body metabolism of radioactive folate tracers, we have now observed that some forms of isotopically labelled folate are biologically distinguishable from the unlabelled carrier molecules by an as yet unidentified secondary isotope effect. Folates excreted in the urine of rats dosed previously with mixtures of ^{14}C- and ^{3}H-labelled folate derivatives are apparently ^{3}H enriched, that is contain more ^{3}H than ^{14}C relative to the dosed compound. This apparent ^{3}H enrichment was largely due to the enhanced absorption of ^{3}H-folate from the intestine, confirmed by studies with everted sac preparations of rat jejunum in which it was found that the ^{3}H-labelled folate in the mixture was transported from the mucosal into the serosal compartment at a faster rate than both the ^{14}C-labelled folate and the unlabelled carrier. Secondary isotope effects were also observed on ion-exchange chromatography, ^{3}H-labelled folates with ^{3}H at the C-9 position eluting fractionally earlier than the corresponding unlabelled or [2-^{14}C]folate from DEAE-cellulose, a behaviour similar to that reported earlier for isotopically labelled 2-aminopurine[1] and several amino acids[2]. Such isotope effects may be more widespread and more important than is generally accepted.

Folic acid (Fig. 1) is commercially available (Radiochemical Centre) in three radioactively labelled forms: labelled with ^{14}C (at the C-2 position) or with ^{3}H, either nominally (at the 3′, 5′, 7, 9 positions, with 33.2% at C-9) or generally (at the 7, 9 positions only, with 41% at C-9). Extensive catabolism of the folate molecule occurs *in vivo*[3] and therefore, to facilitate metabolite identification and quantification, we routinely use mixtures of ^{14}C- and ^{3}H-labelled folate tracers in our whole animal studies.

Urine collected 0–48 h after the administration of mixtures of [2-^{14}C]- and [3′, 5′, 7, 9-^{3}H]folate (10–100 μg per kg body weight) to rats contains a large excess of ^{3}H over ^{14}C whereas faecal samples contain more ^{14}C than ^{3}H compared with the dose[4]. Chromatographic analysis on DEAE-cellulose and Sephadex G15 revealed that the catabolites present in the urine that were labelled with ^{3}H only ($^{3}H_2O$, *p*-acetamidobenzoate

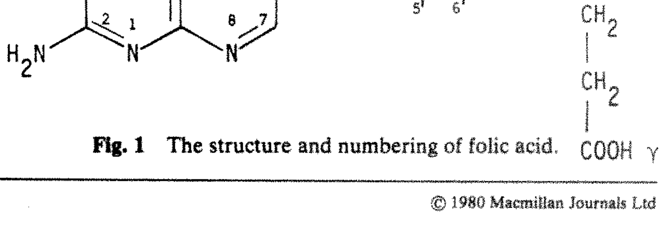

Fig. 1 The structure and numbering of folic acid.

and *p*-acetamidobenzoyl-L-glutamate) accounted for only 50% of the ^{3}H excess, the residue being due to an enhanced ^{3}H to ^{14}C ratio (compared with the dosed compound) of the intact folates excreted (largely 5-methyl-5,6,7,8-tetrahydrofolic acid, 10-formyl-5,6,7,8-tetrahydrofolic acid and unmetabolized tracer). The evidence indicated that either ^{3}H-folate was being absorbed faster or that [2-^{14}C]folate was being absorbed more slowly from the intestine with respect to unlabelled folate. Everted sac preparations of rat jejunum[5] were incubated for 30 min with radiolabelled 10-formyl folic acid, folic acid or pterin-6-COOH and the serosal fluid examined by HPLC. For each of the intact folates examined, an increased serosal ^{3}H to ^{14}C ratio was found compared with the starting material (Table 1). The ^{14}C specific radioactivity of the folate in the mucosal and serosal compartments remained constant. As enhanced ^{3}H-folate absorption was even more pronounced when mixtures of [2-^{14}C]- and [7,9-^{3}H]folate were used compared with mixtures of [2-^{14}C]- and [3′,5′,7,9-^{3}H]folate, the effect was due to the ^{3}H atoms at the 7 and 9 positions. Because the ^{3}H to ^{14}C ratio remained constant in the serosal and mucosal compartments when mixtures of [2-^{14}C]- and [7-^{3}H]pterin-6-COOH (synthesized from a mixture of [2-^{14}C]- and [7,9-^{3}H]folic acid[6]) were used, the important site seems to be position 9, although this assumes that the pterin-6-COOH is transported by a similar mechanism to that of folate.

The isotope effect is not confined to biological situations. When mixtures of [2-^{14}C]- and ^{3}H-folate are eluted from DEAE-cellulose columns, the ^{3}H to ^{14}C ratio decreases across the peak, that is, ^{3}H-labelled molecules elute slightly faster than the ^{14}C-labelled molecules. Similar separations of mixtures of isotopically labelled compounds have been reported previously. We analysed our chromatographic data by the method of Klein *et al.*[7] using the Probit transform to provide the values M (the volume at which 50% of the compound has eluted), ΔM (the difference between the value of M for the unlabelled and labelled compound) and $\Delta M\%$ $[(\Delta M/M)\times 100]$ (Table 2). Graphical plots of the Probit transform of the cumulative percentage of the compound eluted against elution volume gave a series of parallel lines for the unlabelled and corresponding radioactively labelled compounds, demonstrating their homogeneity and absence of co-chromatographing impurities. For all folates examined, the ^{14}C-tracer and the authentic unlabelled compound (measured from its UV absorbance) were well matched, with ΔM values close to zero, whereas the ^{3}H-tracer eluted before both of them (Table 2). We have also observed similar though less marked mismatches on Sephadex G-15 chromatography (data not shown). The chromatographic data confirm the conclusion reached from the everted sac studies that ^{3}H incorporation at the C-9 position is the important factor in the aetiology of the isotope effect, as $\Delta M\%$ for [7,9-^{3}H]folic acid was greater than for [3′,5′,7,9-^{3}H]folic acid and was negligible for [7-^{3}H]pterin-6-COOH in similar conditions (Table 2). The role of the C-9 ^{3}H is also emphasized by the decrease in the size of the isotope effects on formylation at the N-10 position.

Table 1 The relative amounts of ^{3}H-labelled, ^{14}C-labelled and unlabelled pteridines transported into the serosal compartment by everted sac preparations of rat jejunum

Compound and isotope mixture	^{3}H:^{14}C ratio		^{14}C:absorbance ratio	
	Starting compound	Serosal compound	Starting compound	Serosal compound
[2-^{14}C]folic acid, [3′,5′,7,9-^{3}H]folic acid and unlabelled folic acid	1	1.25	1	1
[2-^{14}C]folic acid, [7,9-^{3}H]folic acid and unlabelled folic acid	1	1.29	1	1
[2-^{14}C]10-formyl folic acid, [3′,5′,7,9-^{3}H]10-formyl folic acid and unlabelled 10-formyl folic acid	1	1.10	1	1
[2-^{14}C]pterin-6-COOH, [7-^{3}H]pterin-6-COOH and unlabelled pterin-6-COOH	1	0.98	1	1

Everted rat jejunal sacs were incubated with 1 mM solutions (containing 0.1 μCi each isotope) of the appropriate mixture for 30 min. The combined serosal fluid (from three sacs) was then applied to a Whatman Pastisil 10 SAX Magnum 9 HPLC column (50 cm × 0.94 cm) and eluted with 0.10 M potassium phosphate buffer, *p*H 5.0, at 600–800 p.s.i. to resolve transported unmetabolized starting material from any contaminant metabolites. The isotope content was determined by scintillation counting and unlabelled compound from its UV absorbance at 254 nm. The ^{3}H: ^{14}C ratios in the derivatives found in the tissue at the end of each experiment were similar to those of the serosal compartment.

Table 2 The effect of isotope substitution on elution from DEAE-cellulose ion exchange columns

	ΔM (ml)	$\Delta M\%$
[2-^{14}C]folic acid	No separation detected	
[3′,5′,7,9-^{3}H]folic acid	−4.30	1.59
[7,9-^{3}H]folic acid	−5.10	2.02
[2-^{14}C]10-CHOFA	No separation detected	
[3′,5′,7,9-^{3}H]10-CHOFA	−0.45	0.26
[2-^{14}C]5-MeTHF*	No separation detected	
[3′,5′,7,9-^{3}H]5-MeTHF*	−1.25	0.47
[2-^{14}C]pterin-6-COOH	No separation detected	
[7-^{3}H]pterin-6-COOH	No separation detected	

Mixtures of ^{14}C- and ^{3}H-labelled compounds (0.1 μCi each isotope) and unlabelled carrier (5 mg) were applied to DEAE-cellulose columns (1.5 cm × 30 cm) and eluted with a 0–1.2 M NaCl gradient in 0.05 M sodium phosphate buffer, *p*H 7.0. The ^{14}C, ^{3}H and UV absorbance of each fraction (5 ml) was determined and the degree of isotope fractionation calculated. Values of ΔM are quoted with respect to the elution position (M) of the unlabelled carriers; in the calculation of $\Delta M\%$ the sign is artificially reversed to indicate the displacement of labelled from unlabelled compound in the conventional manner. The approximate elution positions of the carriers are: folic acid, 265 ml; 10-CHOFA (10-formyl folic acid), 175 ml; 5-MeTHF (5-methyl-5,6,7,8-tetrahydrofolic acid), 199 ml; pterin-6-COOH, 208 ml.

* Isolated from rat urine after oral administration of ^{14}C- and [3′,5′,7,9-^{3}H]folic acid.

The C-9 ^{3}H-folate derivatives behaved as if they carried an effective net reduced charge, as they eluted early from anion-exchange columns at neutral *p*H. Several mechanisms have been proposed to explain isotope effects of this type. Gottschling and Freese[1] suggested that an unspecified electronic effect, resulting in a change in the *p*K value of the amino group, was responsible for the chromatographic separation of ^{3}H-labelled 2-aminopurine from unlabelled 2-aminopurine. More recently, Klein and his co-workers[2] have provided evidence that isotope-induced changes in hydrogen bonding and local solvent structure may be important. Similar conclusions have been reported[8] for isotopic separations of a variety of deuterated and unlabelled hydrocarbons by hydrophobic HPLC where differences in C–H and C–D bond perturbation by solvent was considered crucial. Isotope-related changes in solvent/bonding effects would obviously be important in folate–protein interactions, either directly, if, for example, the C-9 position was involved in bonding, or indirectly, by contributing to an effective overall decrease in the net charge of the folate molecule. Because incorporation of a ^{3}H atom at the C-9 position leads to a pronounced effect on the transport of folate across the intestine, careful screening for secondary isotope effects is essential in enzymatic and metabolic studies involving such tracers.

MATTERS ARISING

Ordering of FeNi in clear taenite from meteorites

CLEAR taenite in meteorites[1] contains 48–57% Ni and is optically anisotropic[2], unlike taenite (γ Fe,Ni) which is isotropic. We have proposed[2] that clear taenite is composed of ordered FeNi, a phase first identified in iron meteorites by Albertsen *et al.*[3]. Mehta *et al.*[4] have obtained additional evidence for ordering in clear taenite from their electron-optical studies of a large grain, which one of us (R.S.C.) discovered in the Estherville meteorite. However, they interpret their data to indicate that clear taenite is composed of regions of ordered FeNi, which are 1–3 μm in diameter, in a matrix of disordered γ (taenite) of similar composition. We argue here that this conclusion is in all probability incorrect.

On ordering of FeNi, cubic taenite inverts to the tetragonal CuAu or $L1_0$ structure. Because of this symmetry change, three sets of intergrown crystallites of ordered FeNi, which are oriented in mutually perpendicular directions, form from a single crystal of taenite. These crystallites, which can be observed in reflected light under crossed polars[2], are typically 1–10 μm in diameter.

Mehta *et al.*[4] observed extra superlattice diffraction spots from the $L1_0$ structure in preferentially thinned regions of clear taenite in which the [110] direction was parallel to the electron beam. The thicker regions which did not show extra diffraction spots were interpreted by Mehta *et al.* to be disordered γ. We suggest instead that the thicker regions actually contained sets of ordered crystallites with [101] and [011] directions parallel to the beam. On the original taenite axes, the unit cell of ordered FeNi is C-centered and has dimensions which are very close to those of taenite[3]. Ordered crystallites with [101] and [011] parallel to the beam would therefore show diffraction patterns that are indistinguishable from those of disordered γ. Thus we are confident that Mehta *et al.* misidentified ordered FeNi crystallites as disordered taenite. If we are correct, all regions of {100} sections of clear taenite will show extra superlattice spots, as in this orientation all three sets of crystallites show superlattice diffraction spots.

Although they acknowledge that our interpretation is consistent with their data, Mehta *et al.*[4] strongly emphasize their own conclusion that clear taenite contains ordered FeNi regions in a disordered γ matrix. Other contrary evidence is provided by Mössbauer[3,5] and optical[2] studies of meteoritic metal, which have failed to detect disordered γ of the size, composition and abundance that Mehta *et al.* propose. We still conclude[2,6] that clear taenite is a new mineral, ordered FeNi.

Differences in fluidity between bilayer halves of plasma cell membranes

ASYMMETRY in the composition of membrane bilayer halves raises the possibility that the individual monolayers have independent physical properties. Recently, Shroeder[1] proposed a method for analysing the fluidity of the individual monolayers of tumour cell plasma membranes. He used an impermeable reagent, trinitrobenzenesulphonic acid (TNBS), covalently linked to outer monolayer amino groups, to quench the fluorescence of *trans*-parinaric acid, a probe which distributes in both monolayers. He contends that the fluorescence of the outer monolayer was quenched and that the elevated polarization of the residual fluorescence reflected a lowered mobility of the *trans*-parinaric acid located in the inner monolayer.

We suggest that TNBS linked to outer monolayer phospholipid amino groups quenches the fluorescence of *trans*-parinaric acid in the two monolayers to a different extent. Because any energy transfer process reduces the donor probe fluorescence lifetime[2], the observed elevation of the polarization of the unquenched *trans*-parinaric acid fluorescence may reflect the impact of the transfer process on fluorescence lifetime[3] rather than probe mobility. Our arguments are based on the following considerations.

(1) The width of membrane lipid bilayers (between opposite polar headgroups) is generally agreed to be less than 50 Å (ref. 4). (2) *trans*-Parinaric acid, 9, 11, 13, 15, all *trans*-octadecatetraeonoic acid is an extended molecule, orientated with its carboxyl group near the polar headgroup. We expect the relatively inflexible tail of *trans*-parinaric acid to be near the middle of the bilayer with the midpoint of its transition dipole (between C-12 and C-13) ~6 Å to either side of the centre of the bilayer. (3) R_0, the distance at which energy transfer between parinaric acid and covalently linked TNBS is 50%, is calculated by standard procedures[5], applicable to membrane bilayer energy transfer to be 23 Å. (4) For a bilayer 48 Å wide, *trans*-parinaric acid chromophores in the outer and inner monolayers will be ~18 Å (0.78 R_0) and 30 Å (1.3 R_0), respectively, from the trinitrophenyl chromophores. (5) With the geometry specified above, we calculate by the method of Wolber and Hudson[6] that, to achieve the 44% reduction of fluorescence of *trans*-parinaric acid by energy transfer between *trans*-parinaric acid and TNBS reported by Schroeder, a TNBS surface density of 0.6 TNBS/R_0^2 is required. The calculations show that ~60% of the outer monolayer and ~27% of the inner monolayer fluorescence are transferred. (6) Fluorescence lifetimes are reduced by energy transfer to an extent similar to the detected change in fluorescence quantum yield[2,5]. For isotropically rotating probes, the Weber–Perrin equation[7] predicts that the lifetime changes in *trans*-parinaric acid caused by the presence of TNBS are alone sufficient to account for the observed elevation of the polarization.

As it seems that the motion of linear probes like *trans*-parinaric acid in membranes is not isotropic[8,9], the extent to which the observed steady-state polarization depends on the probe fluorescence lifetime is a function of both the rate of chromophore motion and its angular extent[3]. These parameters are probably influenced by membrane proteins and cholesterol[10] and can only be extracted by nanosecond polarization measurements[3]. We have, however, observed that the steady-state polarization of parinaric acid probes, confined to the surface monolayer of a serum lipoprotein and quenched by surface-bound energy transfer acceptors, is elevated to an extent comparable to that reported by Schroeder in tumour cell membrane bilayers (L.A.S., unpublished results).

0028–0836/80/380255—02$01.00

We believe that a general validation of Schroeder's method requires absolute proof that only outer monolayer *trans*-parinaric acid is quenched and quenched completely by energy transfer to TNBS. We believe that Schroeder can validate his conclusions about tumour cell bilayers by measuring r_∞, the limiting value of the anisotropy at long times following excitation. Because r_∞ is independent of the fluorescence lifetime and because the residual fluorescence in the presence of TNBS labelling probably arises predominantly from the inner monolayer, an elevated r_∞ in the presence of TNBS would provide good evidence for the difference in the mobility of inner and outer monolayer *trans*-parinaric acid probes.

SCHROEDER AND KINDEN REPLY— We thank Sklar and Doody for their comments and appreciate their concern. It is regrettable that these authors treat a complex biological membrane system, the LM cell plasma membrane, as if it were a model membrane. No experimentally determined values for LM cell membranes were presented. In contrast, we have continued our work in this area and substantiated the use of trinitrophenyl (TNP) groups as fluorescence quenchers and asymmetry determination agents in several systems[1–9]. The erroneous assumptions made in the above critique are as follows.

First, comments (1)–(4) of Sklar and Doody assume the width of the LM cell membrane to be less than 50 Å. In contrast, from micrographs obtained with an RCA EMU-36 electron microscope, we have determined the width of the LM cell plasma membrane to be ~80 Å. Thus, half the width of the membrane would be 40 Å, not 23 Å as proposed by Sklar and Doody. The additional width of the LM cell membrane seems to be due to the presence of proteins. This is especially important because at least 10 times more TNP groups were attached to protein amino substituents than to phospholipids. The fluorophore of *trans*-parinaric acid is about 15 Å from the carboxyl end, similar to the distance of the fluorescent anthroyl group in anthroyl-stearate from its carboxyl end[10,11]. Therefore, quenching across the bilayer would be expected to be less than 0.004 times as efficient as in the outer monolayer. Studies of model systems indicate that there is little energy transfer from one leaflet to the acceptor in the opposite one if R_0 is much less than 40 Å (ref. 12).

Table 1 Fluorescence decay of *trans*-parinarate in LM cell plasma membranes

Cell or membrane treatment	$t_{1/2}$ (ns)	
Untreated membranes	5.9	8.9
Membranes + 100 μM TNP-glycine	5.8	9.1
Pretreatment of whole cells with 4 mM TNBS to trinitrophenylate outer monolayer amino groups[1]	6.0	9.1

$t_{1/2}$ Represents the halftime for decay for each decay component. Plasma membrane vesicles were resuspended in phosphate-buffered saline (100 μg ml^{-1}) and *trans*-parinarate was incorporated as described previously[1]. Trinitrophenylated membranes were prepared also as stated previously[1].

Second, our reported increases in polarization were not due to altered fluorescence lifetime. Evidence obtained with an Ortec 9200 nanosecond spectrometer (courtesy of Dr Lynwood Yarbrough, University of Kansas School of Medicine) showed that the fluorescence lifetime of *trans*-parinarate was not altered. Two decay components in unquenched membranes were observed as shown in Table 1. Addition of 100 μM TNP-glycine to plasma membrane vesicles (100 μg protein per ml phosphate-buffered saline, 24 °C, *p*H 7.4) maximally quenched fluorescence but did not alter the halftimes of decay. TNP-glycine has been used as a non-penetrating quencher in very low-density lipoprotein to quench completely the fluorescence of *trans*-parinarate[3–5]. As shown in Table 1, trinitrophenylated membranes also did not show altered halftimes for *trans*-parinarate fluorescence decay. In all cases of maximal quenching by TNP-glycine or TNP groups attached to the membrane, the fluorescence decay curves were superimposable. In addition, similar data were obtained using a second fluorescence probe molecule, 1,6-diphenyl-1,3,5-hexatriene[2]. Lastly, *trans*-parinarate was incorporated into lipid vesicles made from plasma membrane lipid extracts. The quenching agent TNP-glycine showed no differences in polarization between the inner and outer monolayer. This would be expected because lipid vesicles would have a randomized symmetric distribution of lipid molecules across the bilayer.

Thus, our data in no way support the general photophysical artefact alluded to by Sklar and Doody. Indeed, if the quenching data are artefactual, all three probe molecules (*trans*-parinarate, 1,6-diphenyl-1,3,5-hexatriene and *N*-phenyl-1-naphthylamine) and membranes from cells supplemented with choline, *N,N'*-dimethylethanolamine, *N*-monomethylethanolamine and ethanolamine should have given essentially the same data—increased fluorescence polarization in the presence of quenching agent. This was not the case[2]. *N*-phenyl-1-napthylamine did not show differences in polarization in the presence of quenching agents. *trans*-Parinarate incorporated into plasma membranes from *N,N'*-dimethylethanolamine and *N*-monomethylethanolamine-supplemented cells also did not show differences in polarization in the presence of quenching agents.

This work was supported in part by grants from the National Cancer Institute (USPH CA 24339) and from the American Heart Association with funds contributed in part by the AHA Missouri Affiliate (AHA 78 734).

BOOK REVIEWS

Higher education: retrospect and prospect

Fred Dainton

Higher Education Revisited. By Lord Robbins. Pp.117. (Macmillan: London/ Holmes and Meier: New York, 1980.) £12, $34. *Higher Education for the Future.* By Charles Carter. Pp.160. (Basil Blackwell: 1980.) £7.50. Available from Biblio Distribution Centre, Totowa, NJ, $15.

IN ONE of his many memorable prose passages Sir Peter Medawar has reminded us that, if a science is really advancing, more and more of the facts are correlated by an intellectual framework comprising "general statements of steadily increasing explanatory power and compass" which relieve us of the burden of remembering every fact — the corollary being that books conveying the essence of the subject should progressively decrease in size. By this token the subject of higher education is either not a science or is retrogressing, for what has been written in the past two decades — and there is much — is often lengthy and devoid of generally accepted unifying ideas.

The largest effort in this field, dinosaurian in size (if not in ultimate fate), is that masterminded by the Carnegie Commission on Higher Education, which has resulted in 21 reports and 64 sponsored studies on the average larger than either of the two books reviewed here. Collectively, and in massive detail, the Carnegie publications take a close look at higher education in the USA, with the aim of recommending a way forward which might suffice to carry 'the system' to the end of this millenium.

These two books are as unlike the Carnegie series as could be. They are short, innocent of graphs, unbuttressed by statistics, and the prose of each is simple, direct, unambiguous and pleasingly free from the polysyllabic jargon of the pundits of education and sociology. Both are written by professional economists, and both are essentially personal statements. But there the resemblance ends.

Lord Robbins's book, as befits the elder statesman and Chairman of the Committee on Higher Education which sat for three years at the beginning of the 1960s — the report of which is undoubtedly the single most important and influential document on higher education ever to be issued in the United Kingdom — is an urbane contemplation of those recommendations which were accepted in 1963 in the light of what has happened since in British universities. Sir Charles, the founding Vice-Chancellor of the University of Lancaster and 20 years Robbins's junior, tells us in pithy prose what the whole British 'system' (if that is not too strong a word) of post-sixth-form education is, what he would like it to become and what he thinks may well happen to it by the time he is Lord Robbins's age.

Lord Robbins

Inevitably, some topics are common to the two books. For instance, both touch on student unrest and show their deep revulsion for the methods and aims of the extremists amongst the student militants of the late 1960s and early 1970s which they see as a denial of the academic values of truthfulness and rationality. I would go further than either and assert that the single most important factor in the diminution in public esteem of the universities was the unacceptable behaviour of that tiny minority of militant students which was given wholly disproportionately magnified coverage by the media. This made it much easier for successive governments to restrict the resources they were prepared to make available to universities.

Robbins poses a severe test for any university subject — "Can it be taught so as to enlarge the general powers of the mind?" I don't think I have ever heard this criterion discussed, let alone applied, at any meeting concerned with science curricula at departmental or faculty level, and I feel that some lecturers and textbook authors are so didactic that their influence is mind-constricting rather than expanding. Many of us will draw some comfort from Robbins's statement of "the desirability of working on something that does not at once arouse spontaneous enjoyment". Scientists should also read, mark and inwardly digest what he says about specialization in undergraduate courses. He acknowledges that advances in arts and science come predominantly from specialists but points out that success for the majority of graduates in the western world rests on their broad educational foundations and their versatility, and he recalls the often forgotten qualification to the expansion explicit in the principle of access to higher education by all who are "able and willing" that there should be many more broader courses.

As a Scot, he frequently looks disdainfully southward at the system in England and Wales which forces irreversible specialization on schoolchildren who are far too immature and inexperienced to make wise choices. For 12 years I have been convinced that a broad span of studies in the sixth form is overwhelmingly advantageous even if it necessitates either a longer academic year or more four-year undergraduate courses. A glorious opportunity to do both now presents itself as the size of the 18-year-old age group declines, but I'll wager it will not be seized. Other reforms advocated by Robbins which would help towards this end are a break of at least a year between school and university and, to contain costs, a system of undergraduate student loans, repayment of which would be required only if the annual income exceeded some stated value, an eminently sane and equitable suggestion which would be easy to administer. However, I most strongly disagree with the notion of loans for postgraduates. Were this to become a reality and Research Council and DES studentships to disappear, much valuable research and trained manpower, especially in the sciences and engineering, would be lost, to the detriment of the country as a whole.

Sir Charles Carter

Robbins has much to say that is wise and thoughtful on the value of research, on its relation to and effects (good and bad) on teaching and on the desirable size of institutions — always a matter of subjective judgement rather than logical argument. But I was surprised that he considers universal tutorial teaching to be generally impracticable. Why ever not? Given that the staff/student ratio is 1/9, this means a tutorial load of only 9 hours per week on a one-to-one basis. Surely this or the 4½ hours per week on a one-to-two basis are not excessive additions to the other duties of academics. Including laboratory demonstrating, I did a 22 contact-hour week in Cambridge in 1949 and was none the worse for it.

Lord Robbins's reflections on internal institutional government, on relations between universities and the state (who am I to dispute his high regard for the University Grants Committee?), on the justification of the twin donnish privileges of tenure and freedom to choose his own work, on why more does not mean and has not meant worse, on the binary system and on many other matters, are full of wisdom and experience. Moreover the book has the peculiar charm that each chapter is cast in the form of a letter to a fictitious correspondent who, one surmises, is highly sceptical of the value of higher education. I am reminded of the dictum of Lord Robbins's fellow Scot, Robert Louis Stevenson, that "Every book is, in an intimate sense, a circular letter to the friends of him who wrote it". The reader cannot fail to respond to the warmth and human kindness which lie behind the adoption of this espistolary device and the manifest benignity of the author, factors which — such is the nature of the human psyche — are more persuasive than the statistical data which Lord Robbins freely admits to be absent.

Sir Charles Carter's approach is entirely different. He epitomizes the rational man and is the natural enemy of cant. His prose is precise, crisp and, in some cases, sharp. His arguments command respect for their cogency even if the premises are sometimes mere assertions. He is prepared to question every assumption, overt or covert, on which he considers the British higher education system to be based — there are no sacred cows for him. Whereas Robbins commands attention by charming the reader, Carter, by deflating many of his readers' preconceptions and ascribing qualities of bravery and foolishness to those who attract his approbation or otherwise, may irritate and repel. I would urge those whose initial reaction takes this form to put aside the irritation and to persist, because this is a stimulating book deserving a wide readership.

He starts with a lucid account of the system as it is. Though as faithful to the subject as a photograph, there are illuminating comments, for example, about "social responsiveness" (words much used in the launching of the polytechnics) as really meaning that "public sector colleges are more easily ordered about" (with which I and, I suspect, many US State College and University Presidents would agree) and about how the UGC allocates resources (with which I do not agree). He then delineates the "needs and desires" of society and of individuals, pointing out that society really needs sufficient people with a range of skills able to learn and to adapt quickly, who can be competent citizens, manage change and yet preserve "culture" — defined as "what is worth remembering" and handing on as a legacy to successive generations. After upbraiding Robbins for "a certain sloppiness of thinking" in assigning a "right" to higher education for all the "able and willing", his chapter on the needs and desires of individuals states that intellectual development is not a sufficient individual need and should be balanced by ethical, social and emotional development. That sentiment is, of course, in praise of virtue and against sin but is imprecise and does not lead to any practical conclusion other than the rather lame one that entry tests should not be restricted to cognitive skill. The next chapter raises the question of the wastefulness and inefficiency of higher education, and the need for better planning. Yet, after a scornful look at the Oakes Committee Report as being weak in its recommendations, he seems to reject planning and to welcome overlap of functions between different types of institution on the ground that planners are "insensitive to the need for variety" and are hostile to new ideas, especially if they did not conceive them — no names, no pack drill!

At this point Sir Charles turns to the future, AD 2000, dealing in turn with the sort of institutions we need, the curriculum, research, and the Government as the (inevitable) paymaster. He gives a high priority to Two-Year Community Colleges (an echo of the USA?) and, believing that scholarship is an essential activity for a good teacher whereas research is not, he therefore wants a differentiation of institutions in higher education according to their research roles, with more inter-institutional mobility for students. The longest chapter deals with the undergraduate curriculum, the inertia of which clearly appals him. He sees the essential elements as a specialist core, related subjects, optional courses (which seem to be directed towards making better citizens) and "the examination of some implications of the specialist studies", though the possible nature of these "implications" is, regrettably in my view, left as an exercise for the reader. He writes much common sense on teaching methods and shares my often-repeated view on the invalid reification into a 'subject' of an area of knowledge divided from the rest for the convenience of the division of labour. Examinations are regarded as necessary but he sees much room for improvement in diagnosing the strengths and weaknesses of candidates.

The word 'research', which he regards as a portmanteau containing many different meanings, next comes under his critical scrutiny. He regards it as being of little value in relation to teaching and as a narrowing activity for many, involving little opportunity for originality and independent critical thought. We all have our views on these matters, but he is surely right when he argues for removing the contractual burden 'to research' from university teachers and for a more positive research policy both nationally (which would carry with it the institutional differentiation mentioned above) and within institutions. But he says nothing about the criteria which such policies should satisfy.

To achieve these reforms Sir Charles proposes new machinery including a Higher Education Grants Committee maintaining contact with institutions through a regionally based inspectorate (*sic!*), a single governing body instead of the usual academic senate and predominantly lay council. The members of the governing body would be chosen more for competence than their representativeness. Twenty-five per cent of the revenue of institutions should come from fees in order to remind everyone that costs should be adjusted to output, though this would in fact provide an unhealthy incentive to maintain student numbers irrespective of quality and reduce the influence of the Grants Committee as a regulatory instrument. He also wants loans for students at least for the third and later years. Finally, after a brief encounter with Illich, a conclusion that technology will not cut the ground from under traditional institutions (which, however, ought to teach for 40 weeks per year rather than 30) and the advocacy of a *right* of access to holders of two GCE A-Level passes, Sir Charles proffers us views of what would happen in the next 20 years.

One wonders why this last chapter was written, for I could find nothing new in it other than a *cri de coeur* for more people "to ask awkward questions" and a means for them to do so. But, if this is the necessary condition for change, and if one cannot invent people to do this or if the present system fails to produce them, does that mean we must endure the inertia he so deplores? I do not believe so, for I have more faith in the institutions and the individuals within them to change, but both need the stimulus of books like these. □

Sir Fred Dainton is a chemist who was Vice-Chancellor of Nottingham University from 1965 to 1970 and Chairman of the University Grants Committee from 1973 to 1978. He is currently Chairman of the National Radiological Protection Board and the British Library Board.

Beyond Tansley's 'ecosystem'

Peter D. Moore

Grasslands, Systems Analysis and Man. Edited by A. I. Breymeyer and G. M. Van Dyne. Pp.950. (Cambridge University Press: 1980.) £65, $140.

IT IS now 45 years since A. G. Tansley coined the term 'ecosystem'. The concept of looking at nature as an integrated whole, with intricate connections between its various component parts, both living and non-living, has now been exploited to an extent which is no doubt far beyond Tansley's wildest dream. The limitations of purely mental models have now been cast aside with the advent of sophisticated computer analogues and precise mathematical analysis. Consequently, the work of the International Biological Programme (IBP) has been designed, carried out and assembled using a systems approach to the ecology of various habitats.

The book reviewed here is a further addition to the various syntheses of IBP data which are currently being published and it is concerned with grassland ecosystems. It differs from the previous volume, *Grassland Ecosystems of the World* edited by R. T. Coupland (reviewed in *Nature* **283**, 317; 1980), in that it is concerned with seeking a description of common processes within grasslands rather than with surveying the variations within the world's grassland types. It is thus a book in which the systems analysis approach to ecosystem study is fully developed and illustrated. Since it has involved 38 different authors from all over the world, it must have been a headache to edit in order to maintain some uniformity of style and approach.

The book is arranged in three parts. In the first, the total system is analysed into its components — abiotic, autotrophic, small and large herbivore, invertebrate and vertebrate predator, and decomposer subsystems respectively. In the second part, the ecosystem is assembled and such total system processes as nutrient cycling, energy flow and trophic structure are considered. Finally, in Part III, the use of the systems approach in the management and exploitation of grassland ecosystems is discussed.

The general approach of editors and authors has been to begin with a simple, easily conceived, low-resolution model of the various systems and subsystems covered and to develop it and elaborate it as necessary. One danger with this is that the initial model can become oversimplified to the extent that it is no longer helpful. This is the case, for example, in the general ecosystem model presented by Breymeyer in the Introduction, in which energy and matter are not separated and both appear to cycle. Hinds and Van Dyne, however, use the same technique very effectively when describing the abiotic subsystem of the grassland ecosystem. Taking water movements, they construct a simple, low-resolution model involving only three components and then expand it to illustrate the complexity of subcomponents within these major divisions and, even more important, the intricacy of likely paths of water movement within such a high-resolution model.

All chapters have strongly developed review components and each is equipped with its own bibliography. Thus, for example, the chapter on the autotrophic subsystem by Singh *et al.* reviews the various models which have been developed to describe the photosynthetic process and its relationship to environmental factors. Particular attention is given to the Waggoner, Chartier and Lommen models of carbon uptake by the leaf.

Among the herbivores, it is evident that there is considerably more information concerning the large herbivores than the small (invertebrates). For the former, a great deal of interesting information is collated, relating not only to energy flow within the large herbivore, but also to food selectivity on the part of many such grazers.

Ecologists concerned with the practicalities of grassland management, rather than the satisfying symmetry of computer-drawn curves, will also find something to interest them in this book. Data are presented from experimental grazing trials in the USA which examine such subjects as the influence of stock density upon floristic composition.

Overall, the book leaves two lasting impressions. One is the value of the systems analysis approach to understanding processes in the ecosystem. The second is the advantages gained by an international approach to the development of such models for habitats with similar structure and life-form composition. In this way one can proceed beyond the high-resolution, complex model to general statements concerning the function of such an ecosystem and the nature of the global variation upon the general theme. This volume, with its predecessor, Vol. 18 in the series, represents a significant step towards this goal. □

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences at King's College, University of London.

Reviews of galactic research

C. Pritchet

Photometry, Kinematics and Dynamics of Galaxies. Edited by D.S. Evans. Pp. 492. (Department of Astronomy, University of Texas: 1980.) $16 + postage.

THIS volume reports on a conference that was held in Austin, Texas, in August 1979. The proceedings of the conference communicate the current excitement over 'nearby' galaxies — a field of research (once considered prosaic by many) that has been transformed by a new generation of technology.

Many of the major scientific results that were presented in Austin are in press, or else have already been published. This of course detracts from the usefulness of the conference proceedings, but nevertheless reflects favourably on the scientific importance of the meeting to participants and their co-workers. Of particular interest are papers (by T.X.Thuan and W. Romanishin, and by R.E. Schild and T.C. Weekes) that purport to show that so-called 'cD' galaxies in poor clusters are simply giant ellipticals. Other exciting new results include the detection of a 'thick-disk' component in SO galaxies (by D. Burstein), and the detection of rotation in the bulges of spiral galaxies (by J. Kormendy and G. Illingworth). This latter finding is in contrast to the (now well-known) non-rotation of elliptical galaxies — a result that is considered at length in this volume. Other topics of extensive discussion include the kinematics of HI and HII in spiral galaxies, and the surface photometry of spirals.

Perhaps the most commendable feature of this volume is the presence of several excellent review papers — by S.E. and K.M. Strom (on the effects of environment on the evolution of elliptical and disk galaxies), by K.C. Freeman (on disk galaxies), by M. Capaccioli (on the kinematics of early-type galaxies) and by J. Kormendy (on component analysis of galaxy luminosity profiles). Two other reviews, on galaxy photometry (by G. de Vaucouleurs and by H. Corwin), provide a historical perspective which may well be instructive to younger astronomers. Though somewhat tersely written, the papers in this compendium maintain an up-to-date and authoritative focus on areas of current interest; all will be of some value to specialists and browsers alike.

Photometry, Dynamics and Kinematics of Galaxies can be recommended to all readers with an interest in modern extragalactic astronomy. The editor, D.S. Evans, and contributors are to be commended for making this volume available sufficiently promptly so as to ensure its immediate scientific value. □

C. Pritchet is a Research Associate at Dominion Astrophysical Observatory, Victoria, Canada.

text books from MACMILLAN PRESS

FROM DNA TO PROTEIN: The Transfer of Genetic Information
MARIA SZEKELY

This is the first textbook which discusses gene structure on the basis of recent discoveries of overlapping and split genes and which genetic information can be encoded into the genetic material and how it can be transferred to other materials.

A perfectly up-to-date account of our present knowledge of the structure and expression of genes in prokaryotic and eukaryotic organisms and the only available text showing the correlation between the structure and function of nucleic acids.

March, £18.00, 0 333 21836 1
£9.95, 0 333 21828 8

HUMAN REPRODUCTION AND DEVELOPMENTAL BIOLOGY
D. J. BEGLEY, J. A. FIRTH and J. R. S. HOULT

An integrated approach to describe the cellular and physiological processes of human reproduction and embryological development in relation to their underlying mechanisms and to their practical applications in medicine. The book combines anatomy, biochemistry, physiology and pharmacology, making it more suitable for modern preclinical and human biology courses.

February, £20.00, 0 333 23423 5
£9.95, 0 333 23424 3

GYNAECOLOGICAL CYTOLOGY
MATHILDE E. BOON and METTE LISE TABBERS-BOUMEESTER

Dr Boon and Dr Tabbers-Boumeester have, over the past ten years, developed the course in diagnostic cytology which was first given in Leiden in 1969.

In this volume they present their insight into both the study of diagnostic cytology, and into the teaching of this increasingly important subject. To illustrate the modern concepts of cytopathology, examples of more advanced approaches are included: as well as scanning and electron microscopy there are details of DNA measurements, morphometry and immunopathology.

The evolution of coastal East Anglia

Brian Funnell

The Pre-glacial Pleistocene of the Norfolk and Suffolk Coasts. By R.G. West. Pp. 300. (Cambridge University Press: 1980.) £40, $84.

ANYONE who has looked down an East Anglian estuary, or across the East Anglian tidal flats and marshes of the present day, will readily appreciate the variety of environments represented there. Assume these environments to have been destroyed and re-created three or four times, under alternately cold and temperate climates, at almost identical topographic levels, and you have some idea of the complexity of the deposits which record the history of the pre-glacial coastlands of East Anglia.

The first comprehensive attempt to interpret these deposits was made by Clement Reid, an officer of the Geological Survey of England and Wales, towards the end of the nineteenth century. For half-a-century afterwards little significant further work was carried out on them until P. Thomson applied modern pollen analytical techniques to the West Runton Freshwater Bed. S. L. Duigan's doctoral thesis of 1954 confirmed Thomson's conclusion that the peat bed at West Runton represented an almost entire interglacial cycle, and at the same time revealed the difficulties that would be encountered by anyone attempting a full interpretation of the whole sequence of Cromer Forest Bed deposits. In 1958 Dr, now Professor, R. G. West started work on a full pollen analytical and environmental interpretation of the Cromer Forest Bed Series and his marathon studies are enshrined in this comprehensive monograph.

The book records for posterity, with faithful care, all the problems, difficulties and complexities of the Cromer Forest Bed deposits as they have revealed themselves to one persistent observer over a period of years. Although it is accompanied by a thorough commentary and separate discussion of some general aspects, such as sea-level changes and environmental interpretation, there are no over-slick summaries that would enable a casual reader to raid the book for quick answers on vertebrate or plant community evolution, stratigraphical correlation or sea-level changes. Each piece of evidence is carefully weighed, considered and recorded, but never forced into a simple framework for the sake of easy conclusions. It thus stands as a record of work that is both complete and still in progress.

Most readers would be well advised to arm themselves with a liberal supply of bookmarks to facilitate cross-reference between the text and the numerous tables, plates and figures (the latter conveniently provided as a separate booklet in a back pocket to the book), as these need to be continuously referred to as the text is read. It is indeed one of the attractions of this book that it is not just a presentation of the author's conclusions but also a complete do-it-yourself kit that will enable readers to reassess and reinterpret the basic data which have been so assiduously collated.

Overall Professor West concludes that the Cromer Forest Bed Formation has accumulated during four main pollen stages. The story starts with an account of the last marine transgression of the Norwich Crag Formation, which extended over the Chalk of north-east Norfolk during the initial substage 'a' of the cool Pre-Pastonian. (There is some reference to the earlier pre-glacial marine deposits of the Ludhamian, Thurnian, Antian and Baventian stages in the text, but only to complete the description of a particular section or borehole or to round off comparisons of floras from later stages.)

The Cromer Forest Bed proper begins with the main Pre-Pastonian (sub-stages 'b' to 'd'), which is represented by freshwater and fluviatile deposits containing cool floras occurring at between −3 and + 5m OD. It is followed by the Pastonian stage, containing temperate pollen, sometimes starting and ending with freshwater deposition, but including a substantial coastal marine phase, at levels between −9 and +8m OD. The succeeding Beestonian stage is again cold, with evidence of frozen-ground conditions, but is also in part coastal–marine in origin. Its deposits occur at between + 2 and + 8m OD in a limited area in north Norfolk. Finally the Cromerian stage *sensu stricto* is temperate, substantially freshwater, but with a significant mid-Cromerian marine or estuarine phase, and occurs at levels of between −7 and +8m OD over a wide area. The sequence concludes with early Anglian arctic peaty muds which are sealed in immediately under the first true glacial deposits on the East Anglian coast.

Correlation of the East Anglian stages with comparable stages identified in the contemporary deposits of the Netherlands is still uncertain, probably owing to the close similarity of successive temperate floras at this period in the Quaternary and to the strong influence of local environments on pollen spectra on both sides of the North Sea at that time. The absence of a definitive correlation does not however detract from the intrinsic interest of the detailed ecological and geographical changes which occurred along the East Anglian coast before the arrival of glaciers.

Professor West is to be congratulated on a major work of scholarship, which certainly matches the contribution of Reid and will undoubtedly become a classic in its own right. □

Brian Funnell is Professor of Environmental Sciences at the University of East Anglia.

nature

25 September 1980

What future for European fast reactors?

Of all the neglected technologies of the past few years, the technology of the fast reactor is the most pathetic. Long gone are the days when governments in the industrialized world were declaring their intention of running up one or two demonstration plants confident in the hope that their electricity utilities would then be able to make limitless (and cheap) electricity without much trouble. As the years have gone by, governments have become more and more hesitant, even pusillanimous. In the United States, fast reactor development is in the doldrums — the demonstration reactor at Clinch River consists largely of a collection of components not yet put together, while all but a few of the small-scale reactors being built or operated ten years ago have now bitten the dust. The trouble at Clinch River is partly financial (the cost of completing the reactor would now be far greater than the original estimate), partly technical (the design leaves much to be desired) and partly political — fast reactors are regarded by the US Administration as the doorway to the "plutonium economy" and the rapid proliferation of nuclear weapons to lie beyond that, while fast reactors have become prime targets for those who go about with "No nukes" on their bumper stickers or tee-shirts.

Outside the United States, the desuetude is less conspicuous even though the brash optimism of the 1950s has largely evaporated. There are substantial prototype fast reactors in France, the Soviet Union, the United Kingdom and West Germany, while a reactor capable of generating 1,200 MW of electricity (and called Super-Phénix) is being built in France with financial support from West Germany and, to a lesser extent, Italy. As the months go by, the prospects improve that, by 1983, this reactor will turn out to be the first full-scale reactor of its kind. The French are already talking of the reductions of capital costs that will come about when the sixth or seventh replicas of Super-Phénix are built. Now, it seems, this talk has wooed the UK Atomic Energy Authority away from its long-standing belief in its own supremacy. This, at least, is one reading of Sir John Hill's welcome last week for the proposal that the United Kingdom might join the European collaboration concerned with Super-Phénix (*Nature,* 18 September). The decision now rests with the British government but will also, no doubt, be influenced by the course of the negotiations on commercial terms which are still to be completed. How sensible is this course of action? What, in any case, are the prospects for fast reactor technology? And does it follow that the nuclear business, in France certainly but perhaps in the rest of Europe, is embarked on what many of its critics consider to be a dangerous path?

The proposal that British interests in fast reactor technology should be met within the framework of some wider collaboration is probably not so much a choice as a Hobson's choice. For several years, it has been obvious that no amount of successful operation of the Prototype Fast Reactor at Dounreay would bring into being the heavy industry that would be needed if fast reactors were ever to be built in earnest. The National Nuclear Corporation (now to be reorganized again, but probably to be made more effective in the process) is having to go through all kinds of gyrations to take on the design and construction of a single pressurized water station on which construction cannot begin for another two years. At the same time, to create the capacity for building fast reactors, especially when the demand for these is entirely unknown, would be impossible. Such an attempt would be a folly. On strictly practical grounds, it is prudent to look for some international arrangement under which the labour of building fast reactors could be divided, together with the profits (if any) in doing so. Wider considerations, European collaboration and all that, reinforce the point. So far, so good.

As always, there are several snags. Is Super-Phénix such a mature fast-reactor design that it will be possible, as the French hope, to use it as the model on which to fashion a whole generation of replicas? Or will it be necessary, after 1983, to build yet another demonstration plant, and to incur the substantial extra costs of doing so? Answers to these questions (which cannot be simple) will no doubt help to determine the British government's response to the Atomic Energy Authority's request. The choice, it will be remarked, is again not an open choice between collaboration and going it alone. Given the government's commitment to a public inquiry before a commercial fast reactor could be built, the Atomic Energy Authority would have to kick its heels for a further five years before the construction of a commercial fast reactor could begin. While scratching their heads over these alarming questions, ministers and the management of the AEA should reproach themselves (and/or their predecessors) for having, aloof and toffee-nosed, scorned the proposals for European collaboration on the development of fast reactors in the decade following the late 1950s.

But why the hurry? And what, in any case, is the objective? If, in the United States, nuclear policy is based (as it has been for the past three years) on the principle that the recylcing of nuclear fuel is economically unnecessary, why should European governments be rushing ahead? The French position is clear and characteristic. Self-sufficiency, or near self-sufficiency, is in itself a legitimate goal. The Commissariat à l'Energie Atomique has calculated that it might be possible to generate a substantial proportion of French electricity production from indigenous uranium, but only with the help of breeder reactors extracting fission energy from uranium-238 (via plutonium-239) as well as from uranium-235. This will not, of course, prevent the French from making deals with Australia for the supply of uranium ore (like that announced last week) — that will be a sensible way of eking out supplies. Elsewhere in Europe, self-sufficiency is less obviously a part of public policy, although few European can take much comfort from American assurances that uranium prices will be relatively low (less than £35 per kilogram of U_3O_8) for the remainder of this century. Prices could leap up, as they have done on several occasions in the past, if (or rather when) there is a revival of confidence in nuclear power in the United States. In most European countries, however, there is no immediate need for a fast-reactor programme on the scale now foreseen in France. The most urgent need is that potential users should become so familiar with this new technology that they will be able to handle it confidently. Much also needs to be learned about the economics of fast reactors, and of the fuel cycles on which they are based. The case for pushing ahead quickly with fast reactor technology is that its long-term importance will be demonstrated only when a number of reactors have been used commercially, by European utilities of all kinds.

If this objective were more clearly recognized, some of the present reactions against the building of fast reactors would, or should, be less intemperate than they are. It must, however, be expected that others will persist. Fears for the safety of fast reactors are rife, but, as commonly stated, are often misplaced. It is in everybody's interests that such anxieties as there are should be widely understood. The fact that a core of a fast reactor

0028-0836/80/390263-02$01.00

contains more than enough fissile material to cause a nuclear explosion does not make every fast reactor a potential bomb.

The most likely sources of potential hazard are, on the contrary, mundane — the apparently devilish capacity of liquid sodium to work its way through leaks and cracks, the formation of vapour bubbles in the circulating sodium which can increase the reactivity of the system (at least if it is physically large enough) and the possibility of chemical interaction between liquid sodium and fuel cans or impurities (such as water). The most likely source of criticality problems is not the formation of a single critical mass of fissile material but, rather, mechanical oscillation within the reactor core which, on paper at least, may be symmetrical enough to set in train a sustained and rapid increase of reactor power. The fact that the nuclear reaction involves fast (1 MeV or so) neutrons rather than thermal neutrons is not in itself a source of potential hazard. The power density of the system (400 W per cm^3 in Super-Phénix) does, however, carry heat-transfer engineering into a novel field, while the use of liquid sodium as a heat transfer medium presents another set of once unfamiliar problems. On balance, however, there is no reason to dispute the claim of the nuclear engineers that individual fast reactors need be no more hazardous than conventional reactors. In Britain, the intended public inquiry, unfortunately now delayed at least until 1985, will provide sceptics a splendid opportunity to test the proposition.

Fears that fast reactors mean a greater risk of proliferation are less substantial, and should now be exorcized. The argument is that if plutonium is separated from spent fuel from thermal reactors, stocks of plutonium will increase as will the oportunities for theft and illicit diversion into bomb-making. In its simplest form, the argument perversely overlooks the simple truth that reprocessing facilities are at present few and far between. The bomb-making states, anxious as they are that the nuclear club should not be enlarged, control the only substantial plants now in operation. Others, even that being built in Brazil, are under international control. India is the exception that proves the rule — its reprocessing facilities are uncontrolled, but their capacity is small. In the past year, and especially in the wake of the International Fuel Cycle Evaluation, there has been much talk of internationally operated reprocessing facilities.

Such schemes, imaginative though they are, are not, however, the most urgent needs in the international effort to control proliferation. Certainly the pace of fast reactor development now on the cards is not going to increase the opportunities of governments to join the nuclear club, at least in the remainder of this century. Moreover, given that such plutonium as fast reactor programmes will produce will accumulate in the stockpiles of well-ordered states (and will also, not doubt, be put back into fast reactors as quickly as possible) there is no reason to think that the chances of illicit diversion will be proportional to the total quantity of plutonium in existence. Safety, in brief, is something to worry about. The risk of proliferation at least for the time being, is not.

Technical innocence in the public service

With much of the British Scientific Civil Service still seething over the pay settlement for this year (*Nature*, 24 July), the Civil Service Commission on Tuesday went some way to acknowledging that scientists in the Civil Service often have a raw deal. The publication of the *Review of the Scientific Civil Service (1980)* (Cmnd 8032, HMSO, £6,10), prepared by a group of officials with Dr Martin Holdgate, Chief Scientist at the Department of the Environment, is not pure emollient, however. The remedies which the review suggests, valuable as far as they go, do not touch the problem which many people (not only scientists in the Civil Service) consider the most serious — the continued separation of scientists (and of other professionals) from the Administrative Group, the body chiefly responsible for the formulation of policy within the British government and within which true mandarins grow up. Although, at the higher reaches of the Scientific Civil Service, a handful of posts are considered as "open" grades, it is inevitable that for most people in the public service the Holdgate review will seem to rub salt in open wounds. So too will the date in parentheses at the end of the title, which is an awkward reminder of how often the question has been considered, and to how little effect.

The case for a merger of scientists (and others) in the public service with the administrators is not to feather the nests of scientists, nor to ensure that each and every one of them can look forward, from the beginning of his career, to being a powerful head of a Department of State, with a briefcase and chauffeur to match. Many scientists would in any case prefer to avoid that path. The need is rather that the public service as a whole should be more able to understand the problems of a technical character with which it has increasingly to battle. The Holdgate review acknowledges this need at the outset of its report. It goes on to record the failure, in the past few years, of the schemes devised to help scientists transfer from their ghetto to the Administrative Group. The explanation is, of course, straightforward. Scientists in early or mid-career do not relish giving up their science to become administrators. Afterwards, it is often too late. The Holdgate remedy is that, in planning people's careers in the Scientific Civil Service, care should be taken that promising people should be given training in the "management skills" supposed essential to administration. The trouble is that without a common understanding throughout the public service that posts as administrators would be found for those wishing to transfer, more training may simply mean more frustration. In any case, for as long as most of those responsible for policy-making persist in their innocence of technical questions, the public service will be less effective than it needs to be. This broad question is outside the terms of reference of the Holdgate review, for reasons which are not necessarily sinister. Nobody should forget that it is the question most in need of answering.

If tinkering with the present system can help, however, Holdgate and his men (*sic*) have some useful things to say, especially on the careers of scientists in the public service. Scientists need to know more clearly than at present what their career prospects are, and to be helped (if they wish) to broaden them. Merit needs to be rewarded, especially in those following less glamorous careers such as the provision of technical services. Decorously, the report skirts round the issue of pay, and also timorously accepts that probationary and fixed-term appointments to the Scientific Civil Service would be impracticable. The truth is that they would be unwelcome, which is another matter. The review comes close to acknowledging the need for a more effective scientific contribution to general policy with its plea (to the administrators) that they should more openly look for and welcome scientific advice within the public service. We shall no doubt see (or not see) what happens

What will happen now? The Civil Service Department (responsible for employing all Civil Servants) will urge everybody in sight to follow the Holdgate recommendations. After a few months, or a few years, this review will join its predecessors in the archives of British public administration. The innocence of the Civil Service as a whole of what the modern world is like will be found to persist. It will be forgotten, then, that the Holdgate review included within its terms of reference the question of what the Sciencitific Civil Service is for; its report dutifully includes a list of the duties scientists in the public service perform. Now and again there is a hint that the committee of officials knew it was avoiding a crucial issue — and the recommendation that research extrablishments might be decentralized may absolve it of some blame. But is it not high time that somebody asked seriously how best 17,000 of the most highly qualified scientists in Britain should serve the public interest? Influencing policy is one thing. Making government research establishments more useful is another.

0028-0836/80/390264-02$01.00

US woos African states with science

Washington

Trade, it seems, no longer follows the flag but the lab. Washington's top science administrators departed for Africa last week for a ten-day trip aimed at stimulating scientific and technical cooperation with four "moderate" African states — Nigeria, Kenya, Senegal and Zimbabwe.

The sixteen-person delegation is headed by Dr Frank Press, director of the Office of Science and Technology Policy (OSTP). Other members include the administrator of the National Aeronautics and Space Administration, the acting director of the National Science Foundation and the director of the National Institutes of Health.

The practical goal of the delegation is to sign a number of agreements with the four countries for programmes of mutual cooperation. These range from setting up an experimental rural telecommunications system based on satellite technology in Senegal to a broad programme of vocational training courses for Nigerian science and engineering students in US universities and technical colleges.

The delegation's visit is also part of a broader strategy to strengthen links with four African countries with which the United States currently has the best relations. The intention is to help these countries to gain economic stability by promoting their technical efforts — and this in turn should provide a basis for their political stability.

In at least one case there are pragmatic reasons for the United States to want to maintain close political links. Nigeria is at present the nation's second largest supplier of petroleum (after Saudi Arabia); and continuation of this supply is important for the nation's security.

Some money is to be made available by the federal government so that agreements reached during the visit can be followed through, for example by arranging for the reciprocal visit of African scientists and policy makers to the United States. But for many countries, additional fiscal resources are less important than access to people and institutions in the United States able to help with their development problems.

OSTP expects agreements for cooperation to be signed in fields such as marine sciences, environmental resources, agriculture, remote sensing, satellite communications, alternative energy sources and the management of scientific research and technical information.

Three of the countries — Senegal, Kenya and Zimbabwe — will be able to benefit from financial and technical assistance offered under the term of US aid policies. In the fourth, Nigeria, the average income is above the limit for concessional terms to be permitted, and the United States will be looking for costs to be reimbursed.

Many of the agreements due to be signed cover areas that would have been the responsibility of the ill-fated Institute for Scientific and Technological Cooperation (ISTC). The setting up of ISTC was proposed by President Carter in 1978 and authorized by Congress last year, but because of a dispute with the Senate over funding is unlikely to come into existence. However, Dr Press said that the scope of the cooperative agreements, which will include feasibility studies of a Nigerian-based tuna industry and a project on ammonia-based synthetic fuels in Zimbabwe, will go beyond the role that had been intended for ISTC. The mission, according to Dr Press, has the full and active backing of President Carter, who had for example discussed it with Dr Robert Mugabe, Prime Minister of Zimbabwe, who visited Washington last month.

One disappointment for US — and possibly African — officials is that the delegation will not include Dr John Slaughter, a black who has been nominated by President Carter as director of the National Science Foundation.

After an inter-party dispute in the Senate over whether Republican members should assent to the appointment of Democrat nominees in the last few months before the Presidential election, Dr Slaughter's nomination was approved by a Senate committee last Wednesday, and is expected to move swiftly through the full Senate with little opposition. The delay has meant that Dr Slaughter will not be on the delegation and his place will be taken by Dr Donald Langenberg, the foundation's acting director. **David Dickson**

Still looser UK guidelines

The Genetic Manipulation Advisory Group (GMAG), responsible in the United Kingdom for the administration of guidelines on recombinant DNA research, has taken a substantial step towards oblivion. From now on, according to the latest revision of its guidelines applicable to university and industrial laboratories, experiments planned for the least stringent of the four categories of safeguards will not be scrutinized in advance by GMAG. Instead, the laboratory safety committee will have to carry through the standard GMAG hazard assessment and assure itself that proposed experiments do indeed belong in Category I. Laboratories will be required to inform GMAG in September each year of all experiments carried out under this licence in the previous year.

Sir William Henderson, chairman of GMAG, estimated last week that this step will relieve GMAG of 90 per cent of its present work. Because of rules which allow much other research to proceed once GMAG has been notified, it is estimated that only some two per cent of the experiments now being planned will have to await formal permission from GMAG.

The proposal that laboratories should be granted an annual licence to carry out experiments in Category I was first considered by GMAG in November 1978, at its first radical revision of the guidelines. The committee then considered that further information was necessary before the matter could be decided.

Sir William and other members of the committee are at pains to emphasize that this most recent revision of the GMAG procedures has been made possible by the accumulation of information in the past two years, and especially by evidence that the capacity of genetically manipulated bacterial cells to produce foreign protein molecules is limited. The assumption is that the production of foreign protein molecules from a single *Escherichia coli* bacterium with a foreign gene at a plasmid site chosen for expression will not exceed 10^6. This, the argument goes, provides ways of quantifying the maximum amount of foreign protein produced in the infection of, say, the human gut by genetically altered bacteria. On this basis, the maximum amount of insulin produced in the gut by *E. coli* carrying an insulin gene could not exceed the equivalent of 0.6 units of the hormone, compared with the 20 or 30 units normally circulating in the body.

Laboratory safety committees will be expected to verify such estimates made by those wishing to carry out experiments, and to adjudicate specific proposals for categorization of the experiments concerned. GMAG itself expects that there will be further revisions of the guidelines, no doubt tantamount to further relaxations, in the not too distant future

GMAG's own concerns are increasingly with proposals for large-scale manufacture — although the volume of applications so far has, apparently, been surprisingly small. Sir William considers, however, that both in respect of what GMAG requires from industrial applicants and more generally, British regulation of genetic manipulation is now less stringent than in the United States.

On large-scale production plants, for example, GMAG has taken the view that it is not feasible to enclose 100,000-litre fermentation vats in completely sealed containers or to operate them under negative pressure. Safety assessment, therefore, turns on an on-the-spot appraisal of the manufacturing plant and proposals for its

0028-0836/80/390265-02$01 00

operation.

Although it is too soon to know whether GMAG will or should go out of business, the recruitment of specialists in genetic manipulation to the committee may now become increasingly difficult. The group, in any case, will have its hands full with the scrutiny of proposals for work in categories II–IV of the guidelines procedures, and with the principles for regulating large-scale manufacture. The reconstitution of the Dangerous Pathogens Advisory Group, expected soon, should, however, help to clarify GMAG's long-term future.

Engineering research

Planning for more

Washington

Federal policy-makers are now in the process of deciding whether the National Science Foundation (NSF) can provide an adequate framework for regenerating the health of the nation's engineering efforts. NSF officials are confident that it can. A prominent component of plans for reorganizing the foundation, formally presented last Thursday to the National Science Board responsible for foundation policy, is the creation of a new engineering directorate (see *Nature* 11 September). Applied science, which shares a directorate with engineering, would be distributed among the other research directorates.

Concern for the health of US engineering research has arisen as part of the wider debate about declining productivity and stagnating innovation. Equally important, however, has been what NSF acting director Dr Donald Langenberg describes as an "upsurge of interest" from engineering societies over the state of their profession and the role of federal support.

Both NSF and its critics agree that US engineering is in poor health. A rapidly escalating demand for engineers for large-scale construction projects in the oil and chemical industries has created a national shortage of engineers. This situation will be exacerbated by the demands of new plants to be financed out of the government's $20,000 synthetic fuels programme.

The shortage is reflected in the high salaries paid to engineering graduates, while another result is that few graduates are tempted to stay on at university to do research once they have completed their first degree. Many postgraduate courses are now largely filled with foreign students and NSF estimates that, overall, there are 2,000 empty positions in university engineering faculties.

Some universities are designing schemes to compensate. Carnegie-Mellon University in Pittsburgh, for example, plans to offer loans of $1,000 a month to PhD candidates, which need not be paid back if the candidate stays on and teaches.

However, there is general agreement that more than a piecemeal approach is needed; the question is the form it should take. Dr Leo Young, president of the Institute of Electrical and Electronic Engineers (IEEE), has proposed a "blue-ribbon commission" — somewhat similar to Britain's Finniston Committee — to look at the problems facing the profession.

In Congress, discussion has focused on a bill introduced by Mr George Brown, chairman of the House science and technology subcommittee, which proposes setting up a National Technology Foundation. Mr Brown admits that his proposal has been put forward chiefly as a vehicle for discussing a range of proposals and that a revised bill is likely to be re-presented to the next session of Congress.

However, many engineers have not lost the opportunity to vent their frustrations at what they consider to be a lack of support from the federal government in general — and the NSF in particular — especially in fields outside space and defence research.

"Those university departments supported by the Department of Defense and the National Aeronautics and Space Administration have fared well, while civilian engineering, such as building technology and machinery design, have been neglected" complained Dr Bruno O. Weinschel, head of a private engineering company and secretary of IEEE.

National Science Board chairman Dr Lewis Branscomb of IBM admitted at congressional hearings on the bill that NSF support for engineering may have been weak in the past, but he insisted that this was now being remedied. He pointed out that for the past two years the board has proposed greater increases in the foundation's support for engineering research than for any other area of science.

NSF is hoping that its planned reorganization will go some way towards meeting its critics and will in particular head off any attempt to set up a new, separate institution (which might, in addition to the organization split, also be in a position to compete for funds). At a public meeting two weeks ago, held to discuss the reorganization proposals, Dr Langenberg said that engineering research could benefit financially from having its own directorate. He also hinted that reorganization plans were likely to be accompanied by a request for a significant increase in funds for engineering research when the foundation's budget request for 1982 goes to Congress in January.

Further financial commitments are likely to result from President Carter's decision about how to embrace science and engineering education in US schools and colleges, a report on which was sent to the White House by NSF and the Department of Education last month, and is expected to be made public shortly. But even if the Administration agrees that there is room for a larger role for engineering in the foundation, Congress may take some convincing. In debating the NSF appropriations in July, the House of Representatives rejected a proposal for a 10 per cent increase in funds for the engineering directorate.

The White House report is likely to have a good deal to say about engineering research in American universities and colleges. Although, elsewhere, engineering graduates tend to stay away from doctoral courses, in its United States the demand is still quite high. There is, however, increasing concern about the willingness of potential faculty members to teach.

Perhaps more significantly, the powerful House Appropriations Committee claimed that its restriction of the use of NSF funds planned for various innovation projects was imposed "to ensure that an unacceptable level of unbudgeted items does not erode funding for basic research programmes which is — and continues to be — the *raison d'etre* of the foundation".

These sentiments find an echo, though somewhat muted, within the scientific community. At the public meeting on 13 September, representatives of several of the NSF's advisory committees expressed concern that too great an emphasis on engineering and applied science could put a further squeeze on basic research. Dr Langenberg replied that he felt basic science was sufficiently robust not to be significantly threatened, but not everyone present was convinced. **David Dickson**

Electronic publishing

Keyboard papers

Those who wish to publish a research article in a journal, who are asked to referee a paper or who simply want to read what their colleagues have been publishing may in future have to turn to a computer terminal. The fully electronic scientific journal is still a few years off, however. But a group of British researchers is already beginning to consider its possibilities, in a project supported to the tune of £256,000 by the British Library.

The aim of the project, which begins in earnest in November, is to investigate whether electronic journals might ever be feasible, how much they would cost the user and the type of problems they would pose to users. The leg work is being done by groups at the University of Birmingham Loughborough University. The Birmingham group, under Professor P. Jarratt, will be providing the central computer facility and hardware and software to other participants in the project at a cost of £122,000. The Loughborough group, under Professor B. Shackel, will coordinate the setting up of an experimental electronic journal using the rest of the funds.

About 35–40 people dotted throughout universities in Britain will be collaborating. Each centre will provide its own terminal linked in to the Birmingham computer. The British Library funds will go towards suggest how agencies could do more. And this would require a response, in particular from the National Institutes of Health (NIH), which have broad responsibility for stimulating the applications of research results through technology transfer.

It will not be easy to develop guidelines on ethical issues comparable to those which exist on safety. The federal government has no jurisdiction over the treatment that a private medical practitioner can offer, while the separation of church and state is paramount.

French Science

Same now, more later

Paris

The French budget for science will grow with inflation next year — but it is not quite the bonanza for science that the Secretary of State for Research, M. Pierre Aigrain, was claiming last week.

At a press conference to launch the proposed budget, which goes before parliament at the end of next month, M. Aigrain boasted of an increase of 20.4 per cent in non-salary research spending in 1981. Inflation is running at 14-15 per cent, however, and some of the increase will be delayed until 1982.

Nevertheless, M. Aigrain's news is good news. In the past two years, the minister has lost most applied research, accounting for about half his budget, to the control of the minister of industry, M. Giraud, and there were fears that one result would be reduced growth in the budget for basic science. But in the event, Aigrain said last week, basic science will grow by four per cent more than applied.

The 1981 budget is highly selective, and some areas of research will shrink in real terms. Space research funded by the Centre National d'Etudes Spatiales, for example, will suffer an increase of only 9 per cent in money terms, while FF535.6 million (£54 million) available to Aigrain's own office, the Délégation Générale à la Recherche Scientifique et Technique, for making direct research contracts with universities in 1980 will actually fall to FF471.7 million in 1981. (It should rise again in 1982.)

Some sleight of hand with the budget conceals these facts. Running costs plus "programme authorizations" will indeed grow by 20.4 per cent next year but authorizations include commitments for future years. Actual cash for basic research is planned to increase from FF3,630 million in 1980 to FF4,200 million in 1981 — a growth of only 15.7 per cent, and of the same order as inflation. Nevertheless, the budget commits the government to more spending in 1982. Some important institutions will even do well in 1981.

The main beneficiaries affecting universities are the three principal research agencies, the CNRS (Centre National de la Recherche Scientifique), INRA (Institut National de la Recherche Agronomique) and CNEXO (Centre National pour l'Exploration des Oceans); the fourth, INSERM (Institut National de la Santé et de la Recherche Medicale) just keeps pace with inflation. One objective is to help to renew ageing equipment and INSERM is judged to have done well in this regard in past budgets. CNRS, which with some 8,700 scientists runs many of the leading laboratories, gains 24 per cent in its "operational" budget, INRA 31 per cent and CNEXO 34 per cent.

Certain big projects also do well. There will be FF48.5 million to cooperate with the Soviet Union on a Venera probe to Venus and a FF64.3 million contribution to the European Space Agency Spacelab programme. The budget also allows for the construction of a submarine and other work (FF21.7 million); a start on construction of a fusion reactor (TORE SUPRA) at Cadarache (FF15.5 million) and a start on a hot dry rock geothermal project (FF1 million). In basic physics, the government will contribute to the "second souffle" at the Institut von Laue Langevin (FF5.4 million), the heavy ion accelerator GANIL (FF6.7 million) and the Franco-German Institut de Radio-astronomie Millimetrique (FF22.6 million).

One tangible benefit of the budget will be the creation of 625 new junior posts, 410 of them for scientists and the rest for technicians, engineers and administrators.

The budget also reveals the French commitment to defence research, spending on which has grown by 23 per cent a year since 1977 to reach a level of FF11,000 million in 1980, accounting for 37 per cent of the national spending for research and development. Of this fraction, some 28 per cent is described as "research" proper but only one per cent of this finds its way to universities.

Robert Walgate

Soviet bomb scare

Washington

Reports of a possible violation by the Soviet Union of a 1974 agreement on underground nuclear tests could prejudice negotiations on a Comprehensive Test-Ban Treaty, now expected to be concluded within a few months.

Officials in the Carter Administration are hurriedly trying to check preliminary seismological data indicating that the 1974 agreement, under which the United States, the Soviet Union and the United Kingdom agreed not to conduct underground tests equivalent to more than 150 kilotons of TNT, may have been violated.

According to a report in the *New York Times*, unnamed security aides claim that an explosion detected on Sunday, 14 September, was the largest that had been registered since the agreement came into effect in 1976. Some said it was close to, but still above, the maximum permissible limit; others that it may have been as large as 650 kilotons.

Data are now being collected from as many detection stations as possible to see if this assessment is correct, or if stories in the press merely reflect attempts to discredit the Administration's arms limitations efforts.

Officials in the Office of Science and Technology Policy said last week that it would be about a month before sufficient data were collected to make a reasonable judgement on the size of the explosion, but the Administration's concern has already been expressed by the State Department to the Soviet ambassador

Current negotiations aimed at securing a comprehensive test-ban have become bogged down over defining the limits beneath which it may be impossible to distinguish a man-made explosion from normal seismic activity. In recent weeks, negotiators in Geneva have been expressing optimism that agreement was close, and that a draft treaty could be ready for signature within a few months.

German science

Frontier talk

An agreement on scientific cooperation between the two Germanies might well be feasible, according to Professor Kurt Hager, Chairman of the Education Committee of the Politburo of the German Democratic Republic (GDR). He was addressing the country's Fifth Conference on Higher Education (4 – 5 September) which was convened to discuss the contribution of universities and other higher educational institutions to strengthening the GDR's economic performance in the 1980s.

The suggestion carried the political proviso that development of relations "would be made easier if the responsible circles in the Federal Republic could bring themselves to abandon their . . . non-recognition of GDR citizenship and disregard for the sovereignty of our state".

The conference was attended by some 4,000 delegates from both academic staff and students, and it was not entirely a political exercise. Educational planners in the GDR have recently been paying considerable attention to the training of young scientists. Earlier this year, a working group from the Education Commitee of the Politburo visited a number of educational establishments throughout the country. Following the presentation of their findings, Professor Hager had stressed that the early training of young scientists was a "vital task of far-reaching importance which would have considerable influence on further economic growth". He advocated that steps should be taken to ensure that "specially talented young people fitted for science" are discovered as early as possible.

CORRESPONDENCE

Geothermal power

SIR—The recent News and Views article by Richardson and White (*Nature* 10 July)[1] and correspondence in your columns[2] have been concerned with the relative merits of two ways of using geothermal energy — district heating and electricity generation — and there does not seem to be much to choose between them. According to Richardson and White, "Neither of the schemes is particularly attractive in absolute terms". Certainly, electricity generation directly from a geothermal source at a temperature below 200°C has previously been considered to be uneconomic[3,4].

It was because of this view that Patscentre, some three years ago, proposed a scheme that allowed the possible exploitation of such low-temperature geothermal sources for economical electricity generation if they coincided with sites for conventional power stations, existing or prospective[5]. Geothermal hot water could be efficiently used for feedwater heating in the power stations. I suggested that such a concidence of sites might be found on the Hampshire (geological) sedimentary basin. The idea was taken up by the Central Electricity Generating Board, and a borehole was sunk last year at Marchwood power station, near Southampton. Earlier this year, you reported that an aquifer had been struck (*Nature*, 8 May)[6]. I understand that the geothermal hot water will probably be used in the Marchwood station as an experimental illustration of the proposed scheme.

It is to be hoped that, if successful, this experiment will be the forerunner of an acceptably efficient method of geothermal electricity generation in the UK and elsewhere.

R.V. HARROWELL

SIR — The method of evaluation for the district heating option used by Richardson and White in their article on the use of UK geothermal energy resources (*Nature* 10 July, p.103) is not appropriate for UK geothermal resource conditions.

The Department of Energy Geothermal Energy Group have predicted that geothermal energy sedimentary basin resources in the United Kingdom will be most commonly in the range 65 to 80°C. We have recently completed a study for the Department of Energy examining the use of UK geothermal energy resources which concluded that a supply temperature of 65°C will be adequate to meet space and water heating needs. Underfloor heating systems or large natural convectors could operate with a supply temperature of 65°C to satisfy comfort conditions and achieve a return temperature of 30-35°C. We believe, however, that the optimum solution will arise from forced air convection equipment which could reduce the return water temperature to the geothermal source heat exchanger to 20-25°C and furthermore a proposal is in hand directed by W. S. Atkins and Partners and supported by a major UK heating equipment manufacturer to develop a range of such equipment at competitive price levels when compared to standard temperature equipment.

A further important factor to be considered is that the depth of aquifers containing brine at 70°C is such that it could significantly reduce the cost of the geothermal well compared to an aquifer supplying water at 100°C. We suggest therefore that the findings of Richardson and White be reconsidered.

Models of psychosis

SIR—In a recent News and Views article (*Nature*, 5 June)[1], Snyder expressed the view that phencyclidine — currently all the rage among drug-abusers in the United States — might provide a good pharmacological model of schizophrenia. In the course of his paper he makes a comparison with LSD-25 which, he suggests, is not a good model because it produces perceptual disturbances that are mainly visual in nature, whereas those found in schizophrenia occur primarily in the auditory modality. There is actually no factual basis for that statement; on the contrary, several studies (for example, Young[2]) indicate that the effects of LSD on perceptual, as well as on other psychological, functions, are remarkably similar to the symptoms of schizophrenia. This widely quoted misconception about LSD is only one of many which have led, in my view, to the drug being prematurely rejected as a possible pharmacological model for human psychosis. As I have argued in detail elsewhere[3], I believe a good case can still be made for LSD; though Snyder may be right — phencyclidine may be better.

Educative computers

SIR — We were very interested to read your article "Money to spend" (*Nature* 21 August, p.750) about the government's programme on microelectronics in schools and colleges.

One matter of fact, however, we feel should be put right. The estimate of about one hundred schools owning their own computers is a long way off the mark. A survey carried out in the first three months of the year by ourselves and the Schools Council, in which replies were received from 60 out of 104 local education authorities in England and Wales, showed 663 secondary schools with at least one microcomputer. (In Scotland, the figure at the end of August was over 250.)

Even those figures should be taken as very conservative estimates since numbers are growing rapidly from day to day. We know of one local authority, for instance, which is installing a new machine at its schools at the rate of one a week.

If any of your readers would be interested to have a copy of a brief report of our survey referred to above, we should be pleased to send them one.

Interferonology

SIR — I am writing in response to the note on interferon nomenclature which appeared recently in *Nature* (10 July 1980; **286**, 110).

I recognize that the previous nomenclature is less than ideal because the names ("leukocyte", "fibroblast" etc.) now refer to molecular classes of interferons rather than tissues of origin.

With the foregoing qualification in mind, what is gained by replacing L, F and T with α, β and γ ? If physicists changed the names of the *u, d, s* and *c* quarks, let us say, to *x, y, z* and *t*, absolutely nothing would be gained except the additional complication of memorizing which is which. Fortunately, most physicists, unlike most interferonologists, are aware that such symbols are merely arbitrary denotations for distinct entities and are in themselves meaningless. (As long as there are three interferons, why not Athos, Pothos and Aramis? D'Artagnon would be available if another were discovered.)

Until the structures of interferons are better understood individually and comparatively so that an informative nomenclature can be devised, I fail to see the wisdom in replacing Roman letters with Greek, in substituting one purely arbitrary system with another equally so, and in abandoning a nomenclature which, at least, has the advantage of familiarity.

LEE H. KRONENBERG

Educating scientists

SIR — I fear that your readers may mistake your report strangely entitled "Subject in search of discipline?" (*Nature* 31 July, p.432) for a factual account of Sir Alec Cairncross's report to the Nuffield Foundation on "Science Studies". *Nature* suggests, not least by the tone of the article, that Cairncross's report is critical of "Science Studies". May I remind you of a major recommendation of the report? Cairncross declares that "There is a continuing need for injecting into most science degrees some provision for minor courses covering up to 15 per cent of the curriculum. These should be examinable".

This is strangely at odds with what *Nature* has to say. *Nature* associates the minor courses to which Cairncross refers with "general chat about the social relations of science", suggests that "Much of what is now provided for students under this heading centres around the much talked of Promethean dilemma" and that "teachers are all too often bent on grinding other axes — political, ideological or religious". These assertions are not drawn from the Cairncross report and neither are they true. They are uncomfortably close to the sorts of uninformed prejudices which many of us involved in serious attempts to serve science education have long struggled to overcome.

Nature expresses itself in favour of the enrichment of science education. I am profoundly sorry that it has not chosen to treat more seriously those who believe that they are making some progress towards this end.

The last neanderthal in France?

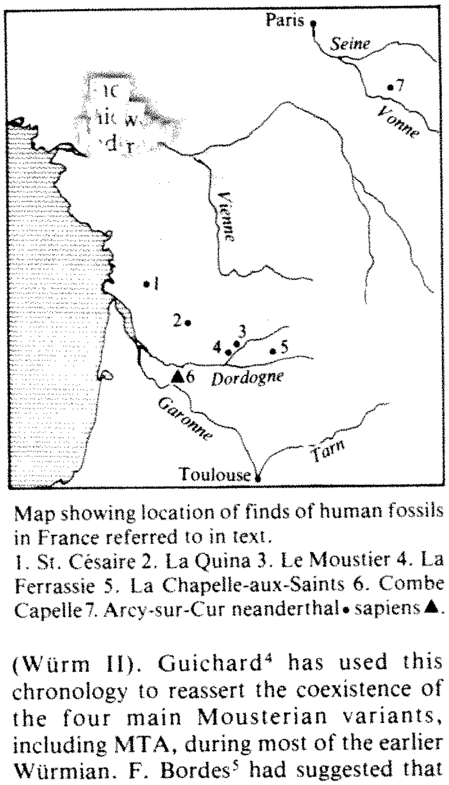
from A.M. ApSimon

THE discovery by Lévêque and Vandermeersch[1] of the fragmentary remains of a skeleton of classic neanderthal type in a Châtelperronian archaeological layer at Saint-Césaire (Charente-Maritime, France), raises once again the problems of the replacement *c.* 34,000 BP of the neanderthal population (*Homo sapiens neanderthalensis)* of western and central Europe by a population of sapiens men (*Homo sapiens sapiens*). Three explanatory hypotheses have been proposed: (1) straightforward evolutionary transformation *in situ* of neanderthal into sapiens; (2) immigration of sapiens leading to the extinction of the neanderthals; (3) sapiens immigration followed by interbreeding in which the distinctive characters of the neanderthals were lost.

Before this new discovery, neanderthal finds from France were exclusively associated with the earlier, Mousterian stone industries (Middle Palaeolithic) characterized by a rich variety of scrapers, knives, spear points and other tools, made mostly on flakes and probably struck using stone hammers. In contrast sapiens were associated with lithic industries (Upper Palaeolithic) in which distinctive long narrow flakes (blades) probably struck off using antler punches played an important role. Although the difference in the industries associated with sapiens and neanderthal suggest they evolved separately, the possibility of *in situ* transformation is not excluded because there are long periods in which the stone industries are without distinctive human remains. In particular, one of the many variants of the Mousterian industries, the Mousterian of Acheulian tradition (MTA) is notorious for its lack of any morphologically distinctive human remains.

Study of the stratigraphic relationships of the different variants of Mousterian industry in SW France[2] suggested that the MTA was relatively late, whereas the known neanderthal remains were relatively early within the earlier part, Würm I–II, of the last glaciation. This would have left a period up to 20,000 years long (c. 55-34,000 BP) from which no human remains were known and during which the transformation to sapiens morphology could have taken place.

Refutation of this argument has come from H. Laville's elucidation[3] of the relative chronology of the sedimentary and climatic phases, as well as of the associated Mousterian industries and human remains, of the early Würmian (Würm I and II) deposits of the caves and rock shelters of the Perigord region of SW France. This has shown that a number of well-known neanderthal finds, including Le Moustier, La Chapelle-aux-Saintes, La Ferrassie and La Quina, date from the later sub-stage (Würm II). Guichard[4] has used this chronology to reassert the coexistence of the four main Mousterian variants, including MTA, during most of the earlier Würmian. F. Bordes[5] had suggested that these variants were the culturally determined markers of distinct ethnic groupings and that evolutionary divergence between these groups could have allowed the emergence of the sapiens lineage, perhaps among the makers of the MTA variant, since this variant showed features foreshadowing Upper Palaeolithic industries. Criticism of Bordes' hypothesis has centred on the extreme improbability of the conservation of separate lineages in an area as small as Perigord through the 40,000 year long early Würmian stage.



Map showing location of finds of human fossils in France referred to in text.
1. St. Césaire 2. La Quina 3. Le Moustier 4. La Ferrassie 5. La Chapelle-aux-Saints 6. Combe Capelle 7. Arcy-sur-Cur neanderthal • sapiens ▲.

L. and S. Binford[6] attempted to break free from the impasse of ethnic *versus* chronological explanation for variability in Mousterian industries, by suggesting that it might be better explained by adaptation to changing environments and by different tool kits being used for seasonally or functionally different activities. Although the Binfords' hypotheses have been faulted by Bordes[7] and others[8] on grounds that include the unrepresentativeness of the material analysed by them, the over-reductive nature of their analysis, the appearance of similar industries in dissimilar environments, the occurrence of long-maintained year-round occupation and the absence of difference between tool kits from open air and from rock-shelter sites, their work remains of capital importance in calling attention to the potential complexity of causal explanations for artefact variability.

Guichard[4] points a way out of this dilemma through his re-analysis of the diagnostic criteria for the different Mousterian industrial facies. This shows that elements are very rarely entirely absent from a given facies, even though the frequency of particular elements may be very low. This has two consequences: first, it serves to reaffirm the essential unity of the Mousterian tradition and warns against reification of the differences discerned by typologists and, second, it removes the necessary implications of ethnic or functional interpretation, and further weakens the argument for *in situ* transformation.

C.B. Stringer's multivariate metrical study of later Pleistocene hominid cranial material[9] also speaks against the idea of transformation since his results show that the classic neanderthals, including those dated to 'Würm II' in France, were less like the sapiens population of Upper Palaeolithic Europe than were the early neanderthals. His conclusion is that they were probably not the ancestors of modern man.

Although the Châtelperronian is usually treated as the first stage of the Upper Palaeolithic in France, Bordes showed that it probably developed from late Mousterian industries, a possibility hinted

A.M. ApSimon is in the Department of Archaeology, University of Southampton.

Transition between Middle and Upper Palaeolithic industries

(Châtelperronian is considered the initial stage of Upper Palaeolithic because of blade technology, Aurignacian is marked by bone spear points and specialised flint scrapers and gravers, Perigordian by developed blade technology. Szeletian (see text) uses leaf shaped flint spearheads and is technologically transitional from Middle to Upper Palaeolithic.)

at by cases of direct superposition of the two industries. Thus the Saint-Césaire discovery need come as no surprise in view of previous suggestions that isolated molar teeth possessing very large crowns with complicated relief found in the Châtelperronian deposits at Arcy-sur-Cure, Yonne (Grotte-du-Renne, layer XI), might be neanderthal rather than sapiens. The only other human fossil for which association with Châtelperronian has been claimed is the fully sapiens skeleton from Combe Capelle. However, an objection has been raised by Asmus[10]. Noting that the Châtelperronian layer in which the skeleton lay was very shallow, she suggests that the skeleton could only have been protected from disturbance if, when the burial was made, some at least of the later, overlying Aurignacian layer was already present (for further discussion see ref. 11).

Radiocarbon dates for Châtelperronian lie between *c.* 34,000 and 31,000 BP, so that the Saint-Césaire find is probably very close in time to the appearance of sapiens men. Sapiens remains occur in Aurignacian deposits for which radiocarbon dates of *c.* 32-31,000 BP are available. Rigaud[12] takes cases of interstratification as showing the contemporaneity and separate identities of Châtelperronian and Aurignacian in both their initial and developed stages. If the extant human remains are representative then there was a period during which neanderthal and sapiens men coexisted in SW France. If the rate of morphological change which this situation would require decisively rules out *in-situ* transformation, we are left with the choice between hypotheses two and three.

For indications as to where our choice should lie, we may usefully turn to evidence from recent hunter-gatherer groups. This suggests that both neanderthal[13] and early sapiens may have been organized in small bands, moving within limited but loosely defined territories and operating open, inter-band mating systems. Where bands were moving in areas not fully occupied by defined territories, contacts with previously unknown bands may have happened from time to time. Initial signalling between groups would probably be visual, and if contact behaviour proceeded along simple formalized lines, difficulties in verbal signalling need not have prevented peaceful contacts between strange bands. Châtelperronian — Aurignacian interstratification and possible artefact interchange suggests that peaceful contact may have been the rule, in which case there is no necessity to postulate inhibitions to neanderthal — sapiens mating. As the present chronology is only reliable to within about a 1,000 years the disappearance of the distinctive cranial features of the neanderthals would appear to be virtually instantaneous. The recovery rate of fossil human remains is so low that the chance of being able to document the change is very small.

To suggest that hypothesis three is the preferred one is not to solve all our problems, for despite new evidence of the evolution of *Homo sapiens sapiens* outside Europe[14] there is no good evidence to show how they spread to central and western Europe by *c.* 34-31,000 BP, nor is there evidence of their appearance in east-central Europe earlier than in France. Those sapiens finds from central Europe which by their attribution to Würm II (for example Mladeč, Moravia) have been supposed to provide such evidence, simply reflect differing applications of the Würm I-II-III system in the two areas and it is clear that they belong to what would be called Würm III in SW France.

Nor is there evidence that the Aurignacian complex appears earlier either in central Europe or in the Near East than it does in France. Dates in the range 40,000-35,000 BP quoted for Upper Palaeolithic assemblages in the Mediterranean and Near Eastern region depend on extrapolation of observed sedimentation rates in cave deposits and cannot be taken as a reliable indication of the origins and previous development of 'the Upper Palaeolithic' in that region. Many workers have seen reminiscences of the Mousterian in the Aurignacian, even though in France there is no evidence of interstratification and only very doubtful evidence of end-to-end contact. In central Europe the Szeletian industry appears to evolve from Middle to Upper Palaeolithic status and association with both neanderthal and sapiens remains has been reported. It is uncertain whether the bone spearheads and Aurignacian elements in the evolved Szeletian reflect contact with contemporary Aurignacian bands, or whether, as Hahn[15] suggests, the Aurignacian can be regarded as a logical continuation of the Mousterian and Szeletian tool kits. In his view some features of Aurignacian assemblages were already present at a low frequency in Mousterian assemblages, increasing in Szeletian assemblages, so that these show a crossover between decreasing frequencies of Middle Palaeolithic and increasing frequencies of Upper Palaeolithic elements, in particular the bone tools. The coincidence of the appearance of sapiens men with the Aurignacian in Europe is hard to resist, but it may still be a coincidence, and in the Near East, sapiens men already occur with Mousterian industries[16] as at Skuhl and Qafzeh in Israel. We should be wise to maintain with Maheu[17] "the denial of any causal connection between physical characteristics and industry or culture" and to refuse explanations for the disappearance of neanderthal man which rely on unverifiable assumptions of the inferiority of his intellectual and social capabilities. □

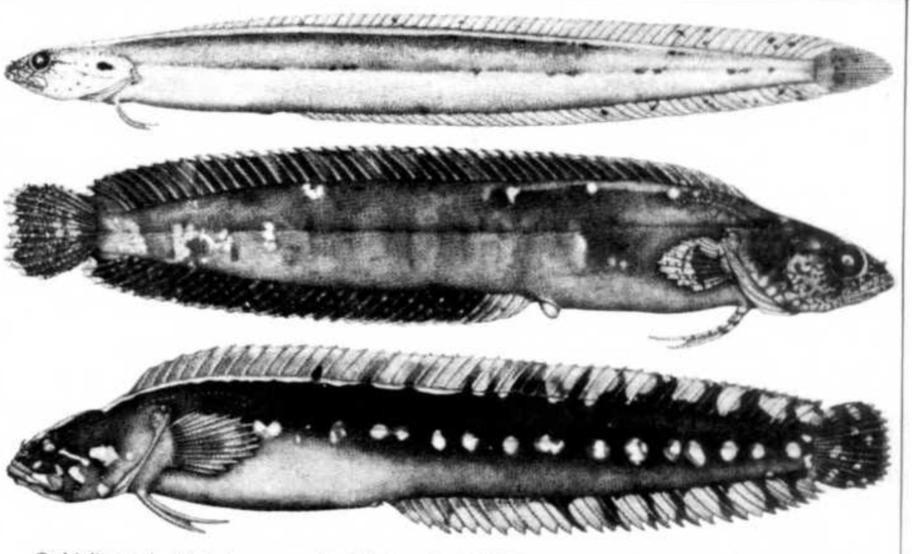
Snakeblennies

from Alwyne Wheeler

The snakeblennies (fishes of the tribe Ophiclinini within the family Clinidae) are small (up to 16 cm long) and live in shallow water along the cool, southern coasts of Australia. They can be captured in tidal rock pools and in bays at depths of 13 m and several species are known to burrow in mud.

A recent taxonomic study by George and Springer* has made a considerable contribution to our knowledge of these fishes, not least because they name no fewer than five previously undescribed species. They have also revised all the previously named species and produced a clarification of the relationships of these little-known fishes. Thus, the species *Peronedys anguillaris* which was previously assigned to a family on its own, and the genus *Sticharium* which hitherto had been placed in the Notograptidae, are now combined with the Ophiclinidae. These fishes are not, however, considered to be distinct from the members of the family Clinidae, which are widely distributed through the tropical and subtropical oceans. For this reason, these southern Australian fishes are placed in a tribe Ophiclinini within the Clinidae.



Ophiclinops hutchinsi, new species (89.0 mm); *Ophiclinus pectoralis*, new species (52.0 mm); *Ophiclinus gracilis* (68.0 mm). Drawings by J.R. Schroeder.

One of the pieces of evidence which substantiates the close relationship of *Peronedys* (which was thought to be distinguished by having no pectoral fins) is that several of the species of *Ophiclinops* have very minute pectoral fins, including the newly described *Ophiclinops hutchinsi* from Western Australia.

Sexual dimorphism and the evolution of higher primates

from R. D. Martin

In this issue of *Nature* Fleagle *et al.* report that three species of primate from Oligocene deposits at the Fayum fossil site show evidence of sexual dimorphism. This discovery has important implications for our understanding of the radiation of monkeys, apes and man as well as enabling us guess something of the social structure of the earliest known Old World anthropoids.

The Fayum fossil site in the Egyptian desert south-west of Cairo is of special significance for the reconstruction of primate evolution. Vertebrate fossils from these Oligocene deposits, dating back some 30 million years, include the first known representatives of the 'higher' primates (monkeys, apes and man). In fact, in the entire African continent, fossil primates from this site provide the only undisputed palaeontological evidence of primate evolution for the first half of the Tertiary epoch (Palaeocene–Eocene–Oligocene). The first fragmentary jaws and teeth of Fayum primates were recorded about 75 years ago and a series of collecting expeditions led by Elwyn Simons (then of Yale University) in 1963–1967 produced a wealth of fossil material from five primate genera (*Apidium; Parapithecus; Oligopithecus; Propliopithecus; Aegyptopithecus*). But soon afterwards events in the Middle East led to suspension of all palaeontological work in the Fayum, and it was not until 1977 that a new programme of joint expeditions was organised by the Geological Survey of Egypt and Duke University. The new initiative has yielded additional material throwing new light on the early evolution of the higher primates.

Interpretation of the initial radiation of the monkeys, apes and man has been thrown into turmoil by new information on continental drift. The traditional view, assuming stable continental positions is that the New World monkeys (platyrrhine) and the Old World monkeys and apes (catarrhines) are two quite distinct branches derived from a prosimian stock spanning the northern continents. The platyrrhines and catarrhines are held to have attained the 'simian grade' independently through parallel evolution. The acceptance of continental drift has, however, generated increasing support for the alternative view that the platyrrhines and catarrhines shared a common ancestor in Africa which had already attained the simian grade. Opponents of this interpretation point out that the first fossil evidence for New World monkeys appears only in the late Oligocene and that the South Atlantic undoubtedly represented a formidable barrier to invasion by terrestrial mammals at that stage. Conversely, reconstructions of continental positions indicate that invasion of South America from North America would have been at least equally unlikely during the Oligocene.

In all of this, the Fayum primates occupy a central position as the earliest relevant fossils. Interestingly, they do show numerous cranial and postcranial similarities to modern New World monkeys, but this is compatible with either monkey or ape origins since the similarities concern primitive features only to be expected in early representatives of the simian grade. It is therefore crucial to determine whether the Fayum primates exhibit specializations specifically linking them to Old World monkeys and apes. On the basis of previous evidence, Simons and his colleagues has already suggested this to be the case. Indeed, Simons proposed that the fossils could be divided into two groups (*Apidium* and *Parapithecus vs Oligopithecus, Propliopithecus* and *Aegyptopithecus*) related to the origins of the Old World monkeys and apes, respectively.

The new primate fossil material from the Fayum deposits has produced no great surprises in taxonomic terms; all of the new specimens can be confidently allocated to four of the five existing genera (*Apidium; Parapithecus; Propliopithecus; Aegyptopithecus*). But the increased sample sizes

for the dentitions of three species (*Apidium phiomense; Propliopithecus chirobates; Aegyptopithecus zeuxis* have permitted identification of a marked degree of sexual dimorphism (Fleagle, J. G., Kay, R. F. & Simons, E. L. this issue of *Nature* p328). For each of these species, the molar teeth of the lower jaws seem to fall into uniform series, whereas the lower canines and anterior premolars show a bimodal size distribution. (The anterior lower premolar has a facet for occlusion with the upper canine and therefore reflects the degree of development of that tooth.) Of course, one must be wary of inferring sexual dimorphism in fossil material, since two separate but closely related species may be involved, and past controversies over the relationships between gracile and robust australopithecines serve as an object lesson here. Fleagle *et al.*, to their credit, made a separate approach by considering the intraspecific coefficient of variation for the depth of the mandible, which was found to be correlated with the degree of body weight dimorphism in a sample of living primate species. On this criterion, *A. phiomense* and *A. zeuxis* were both found to be comparable to modern sexually dimorphic species such as the howler monkey, the proboscis monkey and the gorilla. It is therefore reasonable to conclude that there is good evidence for sexual dimorphism in at least three of the Fayum primate species.

The phenomenon of sexual dimorphism in body size and development of the anterior dentition in living primates has been examined in detail by several authors in recent years (Gautier-Hion, A. *Mammalia* **39**, 365; 1975; Leutenegger, W. & Kelley, J. T. *Primates* **18**, 177; 1977; Clutton-Brock, T. H. & Harvey, P. H. *J. Zool.* **182**, 1977; Clutton-Brock T. H., Harvey, P. H. & Rudder, B. *Nature* **269**, 797; 1977; Harvey, P. H., Kavanagh, M. & Clutton-Brock, T. H. *J. Zool.* **186**, 475; 1978). The following important generalizations about sexual dimorphism have emerged from these quantitative studies: (1) It is always lacking in species living in monogamous family groups; it may or may not be present in species where males have breeding access to more than one female (polygyny); (2) It tends to increase with increasing body size; (3) It is especially prevalent among terrestrial primate species; (4) It is virtually absent among living prosimian primates, uncommon in New World monkeys and markedly present only among Old World monkeys and apes.

From these generalizations it follows that the three apparently sexual dimorphic Fayum primate species were closer to modern Old World monkeys and apes than to modern New World monkeys. In the New World, notable sexual dimorphism is present only in the large-bodied howler monkeys (*Alouatta* spp:), with males weighing approximately 30% more than females. Yet the Fayum primates span virtually the same body size range as the modern New World monkey Family Cebidae (600 g — 6kg; Kay, R.F. & Simons, E.L. *Int. J. Primatol.* **1**, 21; 1980) and exhibit signs of sexual dimorphism even at the lower end of that size range (*Apidium phiomense*). Kay and Simon (*loc. cit.*) have also inferred from the relatively tall molar teeth of one of the Fayum species *Parapithecus grangeri,* that it might have held terrestrial tendencies, though unfortunately there is insufficient dental material to show whether this species was sexually dimorphic. The prevalence of sexual dimorphism (even at quite small body sizes) and the widespread adoption of terrestrial tendencies among the Old World monkeys and apes are probably linked features, and the Fayum primates seem to fit the general pattern.

Further, it seems highly unlikely that the sexually dimorphic Fayum species lived in monogamous family groups and their social systems probably had a polygynous base, as is typical of modern Old World monkeys. Among modern New World monkeys, by contrast, monogamy is common and it has been suggested that this could have been the ancestral condition for platyrrhines. Thus, the new evidence uniformly suggests that the Fayum primates were an integral part of the evolutionary radiation of the Old World Monkeys and apes, as has been consistently maintained by Simons. One must remember, though that the common ancestor of all monkeys, apes and man must accordingly have antedated the Fayum deposits. Palaeontologists generally tend to date the origin of any group from the first known fossils, whereas incompleteness of the fossil record (particularly for Africa during the first half of the Tertiary) allows for a much earlier date. The earlier the actual date of divergence of the platyrrhines and catarrhines, the greater is the likelihood of an African origin of the higher primates.

An understanding of the the relationship between primate sexual dimorphism and social organization is of considerable interest and enables us to suggest the kind of social groups that fossil primates may have lived in. Explanations of why sexual dimorphism evolved have, hitherto, invoked two male-oriented causative influences: (1) intense male-male competition for females, and (2) defence of the social group against predators by large males. However, sexual dimorphism involves divergent male and female strategies and little attention has been given to factors which might favour small body size in females. In an elegant analysis of dental sexual dimorphism in primates, Harvey *et al.* (1978, *loc. cit.*) used relationships between female tooth size and body size as baselines for assessing male dental development ('relative male tooth size') and were able to analyse more precisely the factors associated with exaggerated development

PHYSICS WITHOUT APPARATUS

Acoustical experiments require, for the most part, the aid of some good instrument or valuable piece of apparatus. Nevertheless a few instructive illustrations of the principles of the science can be improvised without difficuly. Firstly, there is the familiar experiment brought into fashion, we believe, by Prof. Tyndall, of setting a row of ivory billiard balls or glass solitaire marbles along a groove between two wooden boards, and showing how their elasticity enables them to transmit from one to another a wave of moving energy imparted to the first of the row, thus affording a type of the transmission of sound-waves from particle to particle through elastic media. Then we may show how sounds travel through solid bodies by resting against a music-box or other musical instrument, a broomstick, or any convenient rod of wood, at the other end of which we place our ear. A kindred experiment, illustrative of the transmission of sounds through threads, is depicted in the Figure. A large spoon is tied to the middle of a thin silken or hempen thread, the ends of which are thrust into the ears upon the ends of the thumbs. If the spoon be dangled against the edge of the table it will resound, and the tones reach the ear like a loud church bell. The thread telephone or "lover's telegraph," is upon the same principle, the thread transmitting the whispered words to a distance, without that loss by spreading in all directions which takes place in the open air.

From *Nature* **22**, 23 September, 488, 1880.

of the anterior teeth in males of certain species (e.g. terrestrial vs. arboreal species and polygynous vs. monogamous species).

Their data also show that, at any given body size, males often have a shorter row of cheek teeth than females, suggestive of lower energy requirements. Significantly, this applies only to species with polygynous social systems and the divergence between males and female increases with increasing body size. Harvey *et al.* briefly mention the possibility that sexual dimorphism may be related to differential dietary strategies of males and females, and the cheek tooth data indicate that this deserves close examination. It has already been shown, through indirect computations based on activity budgets recorded in captivity, that female Sykes monkeys (*Cercopithecus albogularis*) may consume up to 30% more energy than a male, despite the fact that the latter is some 40% heavier (Coelho, A. M. *Primates* **15**, 263, 1974). It is conceivable that divergent energy strategies of females and males may be the primary factor underlying sexual dimorphism in primates and that male strategies in competition for females and anti-predator defence may be conditional upon this. If this is so, then we have firm evidence that such divergence between female and male energetic strategies was present among early relatives of the Old World monkeys and apes at least 30 million years ago. □

Immunological changes in multiple sclerosis

from Barry R. Bloom

At best one may liken the present state of understanding of multiple sclerosis to that of the blind men and the elephant in the ancient Indian legend. A variety of investigations have each touched a piece of the reality, but no one has been able to integrate the observations into a coherent picture of the disease.

Multiple sclerosis (MS) is an inflammatory demyelinating disease found in a variety of clinical forms, ranging from an exacerbating-remitting course to a chronic progressive disease. Not only is the aetiology unknown, but the variety of clinical patterns and immunological pathological changes seen in different patients are so great that there may be more than a single aetiology — a possibility which provides little comfort to either patients or investigators.

There are two principal hypotheses. The first, based on the induction of inflammatory demyelinating disease in animals immunized with central nervous system tissues or myelin is that MS is an autoimmune disease directed against central nervous system antigens. While the classical animal models of allergic encephalomyelitis (EAE) are not faithful reproductions of the human disease, recent models of relapsing EAE in animals (Raine *et al. Lab. Invest.* **31**, 369; 1974; Wisniewski *et al. Ann. Neurol.* **1**, 144; 1977) suggest that autoimmune mechanisms could well contribute to the pathology. The difficulty with this hypothesis is that no convincing evidence for autoimmunity to CNS antigens or myelin components has been found in patients with multiple sclerosis.

The second hypothesis is that MS is caused or triggered by a persistent virus infection. This is consistent with the epidemiology of the disease, and with the finding of elevated antibodies to measles and other viruses in the cerebrospinal fluid of MS patients. Exacerbations and remissions might be explained by emerging antigenic variants, analagous to those seen in the viral demyelinating disease of sheep (Narayan *et al. Science* **197**, 376; 1977; Bloom *et al. Neurology* **28**, 93; 1978).

Whether triggered by immune reactivity to brain antigens or virus, the histopathologic picture of the demyelinated lesions closely resembles that of cell mediated immune reactions, with lymphocytes and marcrophages predominating. However, the often acute onset of symptoms and rapid clinical remissions suggests that mechanisms which are not characteristic of cell mediated reactions, for example, antibodies, immune complexes or edema, are contributing to the disease.

In trying to understand the immunological basis of multiple sclerosis one encounters a frustratingly large number of clues which do not fit into a coherent picture. In particular, there are elevated levels of immunoglobulins, particularly IgG_1, in the cerebral spinal fluid of the majority of MS patients and elevated titers of antibodies are found to a number of viruses, particularly measles. The immunoglobulins found in brain or CSF of MS patients, when subjected to electrophoresis, show a characteristic discrete or 'oligoclonal' pattern of bands. While similar oligoclonal Ig patterns can be observed in samples from patients with several other diseases, (for example, subacute sclerosing panencephalitis (SSPE), viral encephalitides or meningitides, Guillain-Barré Syndrome and neurosyphilis) the banding patterns in MS patients remain constant over long periods while they vary or disappear with time in other diseases. The oligoclonal electrophoretic patterns of immunoglobulins from CSF or acid eluates of MS brain suggest that they may be derived from a limited number of B-cell clones in the CNS.

In this issue of *Nature*, Mattson *et al.* (p311) report that eluates from individual MS plaques or lesions show limited and discrete patterns of immunoglobulin banding, the sum of which appear to be represented in the pattern of pooled eluates from MS brain. In contrast, electrophoresis of immunoglobulins in SSPE brains shows the same immunoglobulin pattern in different portions of the brain, similar to pooled white matter extracts. Mattson suggests that different immunoglobulin-synthesizing clones are present or expanding in different areas of MS brain, raising the possbility that different antigens may be present in each plaque. In another recent paper, Baird *et al.* (*J. Immunol.* **124**, 2324; 1980) have shown that anti-idiotypic antibodies directed against oligoclonal immunoglobulins in the CSF of one patient with MS crossreacted with immunoglobulins from another, suggesting that two different patients had immunoglobulins with similar, if not identical active sites. The paradox posed by these two results is that different patients may have antibodies directed toward the same antigen, as judged by crossreactive idiotypes; and yet different lesions in the same patients may contain different antigenic determinants, or at least, elicit different antibody clones.

Such sweeping conclusions, however, cannot be accepted without serious reservations. While there may be some cross-reactive idiotypes among immunoglobulins in the CSF of some MS patients, a number of investigations have been unsuccessful in finding crossreactive idiotypes in MS patients. In the case of the discrete electrophoretic patterns derived from different MS plaques, it remains unclear whether the changes in banding are merely quantitative, reflecting, for example, merely different accessibility of old, relative to new lesions to infiltration by B cells, or whether there are real qualitative differences in types of immunoglobulin produced in different plaques. It has been reported by Link and Laurenzi (*Ann. Neurol.* **6**, 107; 1979) that individual oligoclonal bands in CSF may contain both κ and λ light chains. This observation, together with the findings of Mattson *et al.* that a number of the bands from different plaques appeared to have common mobility, raises doubts that meaningful conclusions on the number and nature of B-cell clones can be derived from electrophoretic banding patterns of CSF or brain immunoglobulins. An alternative interpretation suggested by Mattson *et al.* is that a mitogenic effect on B-cells of a CNS breakdown product could polyclonally stimulate proliferation of small numbers of B-cells localized in individual plaques to produce 'nonsense'

Barry R. Bloom is Professor and Chairman in the Department of Microbiology and Immunology, Albert Einstein College of Medicine, New York.

0028-0836/80/390275-03$01 00

antibody. While elevated levels of antiviral antibodies are found in the CSFs of the majority of MS patients, little of the antiviral antibody activity is detected on electrophoresis associated with the oligoclonal bands. It remains unclear to what antigens, if any, the preponderance of the immunoglobulins in MS brains of CSF's are directed.

Another clue that must be considered is the significant genetic association of multiple sclerosis with HLA-D, thought to contain the human counterpart to the murine Ir genes. While the linkage to DW2 is strong among patients in Western Europe and North America, patients in the Middle East and Asia appear to have associations with other HLA-D antigens.

In addition to the relatively unique and stable alterations in immunoglobulin patterns in the CNS of patients with MS, recent observations suggest changes in normal cellular immune parameters as well. Con A- and virus-induced suppressor activity of lymphocytes from MS patients have been found to be significantly diminished (Antel *et al. Ann. Neurol.* **5**, 338; 1978; Neighbour & Bloom. *Proc. natn. Acad. Sci. U.S.A.* **76**, 476; 1979). Santoli *et al. J. Immunol.* **120**, 1369; 1978). Recently Reinherz *et al.* (*N. Engl. J. Med.* **303**, 125; 1980) reported a reduction in total T-cells and in T-cell subsets defined by monoclonal antibodies, particularly the T5 subset, in the blood of MS patients during exacerbations. A number of laboratories have recently found reduced capability of lymphocytes from MS patients to produce IFNα (Type I leukocyte interferon) and IFNγ (Type II or 'immune' interferon) (Neighbour *et al. Neurol.* in the press; Riethmuller *et al. 4th Intl. Cong. Immunol.*) and to have reduced natural killer activity (Benczur *et al. Clin. Exper. Immunol.* **39**, 657; 1980; Neighbour *et al. 4th Intl. Cong. Immunol.*). It is interesting to note that a similar, or even more striking decline in ability to produce interferon or carry out natural cytotoxicity, paralleled by decline in the T5 T-cell subset, is being found in patients with lupus erythematosis, suggesting that these changes are not restricted to multiple sclerosis, but common to several diseases of possible viral aetiology.

It is tempting to infer from these various observations that there is a fundamental defect in immunoregulation in multiple sclerosis. Yet in no instance have the immunological changes been clearly associated with any functional changes in the patients. It is not even known whether the immunoregulatory changes precede attacks of the disease, or whether they follow events, still obscure, which trigger attacks. That there are multiple immunologic changes in MS is clear; but which, if any, are directly related to the disease process remains to be established. ☐

Quantum mechanics and gravitational waves

from Bridget Marx

IT has been said that physics is the science of measurement. The quantum mechanical revolution in the early part of this century threw up many problems and paradoxes concerning measurement and, surprisingly, many of these remain unsolved and little understood. It is true that for the most part physics can progress without a full understanding of the practical and philosophical implications of quantum mechanics but occasionally the full impact of these fundamental problems is felt. The latest group to be left worrying about theories of measurement, post quantum mechanics, comprises those people trying to measure gravitational radiation.
